ACT (Continue on reverse side II necessary and identify by block number) The electrochemical reactions, involved in the electro-chemical impregnation process for the fabrication of the cadmium electrode, contain a very complicated sequence of reactions. In this work, the electrochemical impregngtion process was examined both experimentally and theoretically. Experimentally, two sets of potentiostatic transients were obtained for a nickel microelectrode in two different electrolytes. The first set of data was btained in an electrolyte which contained no cadmium ion; the second set tata was obtained in an electrolyte which contained cadmium ions. DD 1 JAN 73 1473 UNCLASSIFIED N SECURITY CLASSIFICATION OF THIS PAGE (When Data Ente

higher current density obtained in the second data set was due to the occurrence of the co-precipitation reaction between cadmium ions and hydroxy ions which were generated by the electrochemical reaction.

Two models, which described the transport process and reactions under two different experimental conditions were developed. The model for a cadmium-ion-free electrolyte was used to identify the rate of the heterogeneous electrode reaction by matching the model prediction with the experimental results. The heterogeneous reaction rate constants so obtained were then used to identify the rate of the homogeneous precipitation reaction by again matching its model prediction with the experimental results.

#### CHAPTER 1

#### INTRODUCTION

Nickel-cadmium storage tatteries have been in use for more than fifty years; since World War II, new design principles have been introduced which have greatly extended their usefulness. Many theories and investigations have been put forward concerning the reaction mechanisms of both cadmium and nickel electrodes. Because the activity of the nickel electrode has been more fully characterized than that of the cadmium electrode, we will focus our attention on the behavior of the cadmium electrode.

There are a number of methods used for the fabrication of cadmium electrodes. These methods are usually classified into three categories: (a) pressed powder or pasted type (1,2,3), (b) impregnated nickel sinter type (4,5,6,7,8) and (c) electrochemical impregnation (9,10,11,12). The last method, however, is simple in operation and can, in theory, achieve high loading of active material in a single impregnation cycle at the lowest cost.

In the electrochemical impregnation process, electrochemically active material is introduced into the porous nickel plaqe by electrochemical precipitation. The plaque, which serves as a cathode, is submerged into an electrolysis cell containing an aqueous solution of cadmium nitrate at a temperature near the boiling point of the solution. The initial pH value of the impregnation solution is adjusted to around 3 by titration with nitric acid. (As the pH value of the bath increases, i.e., becomes more basic, cadmium hydroxide begins to precipitate in regions other than within the pores of the plaque, and active material is lost in the bath, which is not what we want.)

The electrochemical reaction at the cathode during impregnation could either be the liberation of hydrogen,

$$2H_2O + 2e^- \longrightarrow H_2 + 2OH^-$$
, (1)

or the reduction of nitrate ion,

Both reactions produce hydroxy ions which then either diffuse away from the electrode porous surface or react with the cadmium ions present in the pores to form cadmium hydroxide. The cadmium hydroxide then deposits within the pores of the porous plaque.

The precipitation reaction is:

$$Cd^{+2} + 2OH^{-} \longrightarrow Cd(OH)_{2}$$
 (3)

There is the possibility of forming cadmium according to the reduction reaction:

$$Cd(OH)_2 + 2e^- \longrightarrow Cd + 2OH^-.$$
 (4)

This reaction is presumably prevented from taking place by hydroxy ion generated on the electrode surface by reaction (1) or (2), so that there is no chance for cadmium ions to diffuse through the solution onto the surface and be reduced to cadmium metal.

Following impregnation, the electrode is cathodically polarized in a 25 % potassium hydroxide solution with the impregnated plate connected as the cathode and subjected to low direct anodic current (0.25 to 0.75 amp/in<sup>2</sup>). The solution is maintained at about 100°C for a period of from 15 to 45 minutes to convert cadmium hydroxide to cadmium in the pores of the plaque by reaction (4) or to remove any nitrate ion or other undesirable reduction products. The active material of the electrode is presumed to be both cadmium hydroxide and cadmium.

In this work, the electrochemical impregnation process for the fabrication of the cadmium electrode was examined both experimentally and theoretically.

Experimentally, a set of current-density-vs.-time transients at constant applied potential were obtained for a nickel micro-electrode. The current density was due to the occurrence of the electrode reaction (2) and precipitation reaction (3) presented earlier. For the purpose of identifying the electrochemical reactions, another set of current-density-vs.-time transients were obtained using an electrolyte which contained no cadmium ion. In this case, the precipitation reaction (3) no longer took place. The reactions at the electrode were the only reactions taking place.

The transient current responsed in an electrolyte which contained cadmium ions differed significantly from that in an electrolyte which did not contain the cadmium ions. This difference is presumed to be due to the precipitation reaction.

The current obtained in the presence of cadmium ions in the electrolyte at any time was higher than that obtained at the same applied potential in the absence of cadmium ions. This result is explainable by the fact that the cadmium ions in the solution consumed the hydroxy ions which were produced by the heterogeneous reaction (2) and, as a result, promoted the heterogeneous electrode reactions.

The experimental current-density-vs.-time curves obtained in the potential-step experiment were used to identify both the heterogeneous electrochemical and the homogeneous precipitation reaction rate expressions. The heterogeneous rate was identified first from the experimental results in which there was no cadmium ion in the electrolyte. The precipitation rate was then identified from the experimental results in which the cadmium ions were present in the electrolyte.

A set of differential equations which described the transport process in the cadmium-ion-free solution was solved in terms of two unknown constants. The unknown constants, related to the heterogeneous electrode reactions, were identified by matching the theoretical results with the results of the experiment. The precipitation reaction rate constant was then obtained by a similar procedure.

#### CHAPTER 2

#### LITERATURE REVIEW

Impregnation of nickel sinters with cadmium hydroxide, followed by electrochemical reduction to cadmium, is the most economical method by which to fabricate cadmium electrodes. Almost all of the research works concerning this subject may be divided into three types: (a) manufacturing techniques development, (b) impregnation process study and (c) charge-discharge study.

During recent years, manufacturing techniques, especially those involving electrochemical impregnation, have employed widely varying operating conditions (13,14,15,16). There are several parameters that affect the electrochemical impregnation process such as:

- 1) Temperature: Beauchamp (14) emphasized the fact that high impregnation bath temperature keeps the size of cadmium hydroxide crystals small, and thereby obtaining a more active electrode.
- 2) pH value: In Beauchamp's process (14), the pH value was closely controlled by buffering the cadmium nitrate solution with sodium nitrite. Pickett (16) in a similar process, maintained the pH value of the cadmium nitrate bath between 3-5 by titrating the solution with proper amount of nitric acid.

3) Current density: The current density, based on apparent electrode surface, is another important variable. Beauchamp (14) used D. C. current of 4-8 amps/in² while Bulan (15) used alternating current of 1.2-1.6 amps/in² and claims that the electrode impregnated by alterning current technique retained more of its capacity after cycling as compared to electrodes fabricated by other methods. Pickett (16) presents another technique similar to the above and claims that his technique yields higher loading cadmium electrodes and achieves about 85% utilization of the active material.

The electrochemistry of the  $\operatorname{Cd}/\operatorname{Cd}(\operatorname{OH})_2$  electrode in concentrated alkaline solution, typically KOH as in the Ni-Cd battery, has been studied extensively both theoretically and experimentally (17,18,19,20). Bennion, et al. (17) in their theoretical development, present two models, the solution-diffusion model and film model, in considering the failure mechanism in the performance of secondary batteries using metal/metal salt couples. They conclude that one mode of failure of the metal/metal oxide porous electrode is the blocking of the pore or the complete covering of surface by product crystallities. Falk (18) obtained X-ray diffraction patterns from electrodes submerged in electrolyte during charge and discharge by means of a special test cell. He claims that, during charge,  $\operatorname{Cd}(\operatorname{CH})_2$  is successfully transformed into Cd metal in the cadmium electrode, but even after a strong overcharge, this transformation is not

Furthermore,  $\operatorname{Cd}(\operatorname{OH})_2$  is the end product during discharge and there is no evidence of the presence of a CdO film which is believed to be responsible for the passivation of the electrode. Gross and Glocking (19) summarized the results of recent research by characterizing the negative cadmium electrode in a nickel-cadmium cell and evaluating some of the published results about which researchers still disagree among themselves, such as the mechanism for passivation, which is an important phenomena that affects the capacity of the nickel-cadmium cell.

In comparison to the extensive studies on the electrochemistry of the  $\mathrm{Cd}/\mathrm{Cd}(\mathrm{OH})_2$  electrode in KOH solution, there is little information available concerning the electrochemical reactions taking place during the electrochemical impregnation process which uses cadmium nitrate solution as electrolyte. The only research works known to the author are the electrochemical impregnation studies using cycling voltammetry (21,22). They used a 0.013 cm<sup>2</sup> nickel microelectrode and a 0.064 cm<sup>2</sup> cadmium microelectrode. Some important conclusions of their studies are summarized below:

(1) There was a large reduction wave at -0.63V vs SCE(Saturated Calomel Electrode) which appeared only during the initial negative scan. This is believed to be the reduction of a solution species to liberate OH ion in the presence of Cd<sup>+2</sup> to precipitate cadmium hydroxide on the electrode surface.

- (2) A second reduction process was observed at -0.627 vs SCE during the reverse positive scan. This is due to the reductive formation of metallic cadmium from cadmium oxide or hydroxide that was deposited on the electrode surface during the previous forward scan.
- (3) Some processes (or one of the processes) during the first cycle effectively passivated the electrode to further electroactivity. The formation of the gray material at -0.63V vs SCE, discussed in (1), was the most probable reason for the passivation of the electrode.

### CHAPTER 3

#### THEORETICAL APPROACH

### 3.1 General

In voltammetry at constant voltage, the current through the electrolytic cell is measured as a function of time while the potential of the polarized electrode is held at a constant value. The current is affected by both the transfer process and the electrochemical and/or chemical reactions.

A plane electrode is immersed in a solution which contains a substance O. At the imposed potential, O is reduced to another substance R at the electrode surface, according to the following electrochemical reaction:

$$0 + ne^{-} \longrightarrow R$$
 (5)

The current-density-vs.-time curve obtained at a constant voltage depends on both the kinetics of the electrochemical reaction and the rate of mass transfer.

Under our experimental conditions, diffusion is the only mode of mass transfer. The other two modes of mass transfer, namely, migration and convection, are insignificant. Migration

is eliminated by the presence of a large excess of supporting electrolyte which reduces the potential field. Convection is avoided due to the conditions that (1) the solution is not stirred and (2) the duration of electrolysis is short, so that the density change has not yet become a significant factor and natural convection has not taken place.

The dimension of the cell, as compared to the microelectrode used, is so large that the solution may be regarded as extending to infinity; i.e., the diffusion process is semi-infinite.

According to Fick's first law, the flux of the substance 0 at a distance x from the electrode and in the direction perpendicular to the electrode is:

$$N_0(x,t) = -D_0 \frac{2C_0(x,t)}{2x}$$
 (6)

Conservation of the species O leads to the following differential equation:

$$\frac{\partial C_0(x,t)}{\partial t} = D_0 \frac{\partial^2 C_0(x,t)}{\partial x^2}, \qquad (7)$$

where  $\mathbf{C}_0$  is the concentration of substance 0, which is a function of x and t.  $\mathbf{D}_0$  is the diffusion coefficient of substance 0, and is assumed to be a constant.

When the substance 0 is reduced at a very high rate, by imposing a sufficiently large potential step, such that the concentration of this substance at the electrode surface is reduced to zero soon after the start of electrolysis, the boundary condition at the electrode/electrolyte interface for equation (7) is  $C_0(0,t)=0$  for t>0. Initially before the electrolysis, the solution is homogeneous, and the concentration  $C_0$  at t=0 is uniform with the bulk value. The other boundary condition is that  $C_0$  approaches its bulk value when x is sufficiently large.

The electrolysis current is equal to the product of the charge involved in the reduction of one mole of substance 0 by the flux of this substance at the electrode surface. Thus the current density (current per unit electrode surface area) is:

$$I = nFN_O(0,t), \qquad (8)$$

where n is the number of electrons involved in the reduction reaction of substance 0, F is the Faraday constant, and  $N_0(0,t)$  is the flux of substance 0 for x=0.

The solution of the above problem is (23):
$$I = nFD_0^{\frac{1}{2}} C_0^b \frac{1}{\pi^{\frac{1}{2}} t^{\frac{1}{2}}}$$
(9)

where  $C_0^b$  is the bulk value of substance 0.

The current density represented by equation (9) is called the limiting current density of electrochemical reaction (5). This is the maximum current density which can be achieved by this reaction. It was found that if nitrate ion is the only reducible substance, the current density predicted by equation (9) is considerably lower than the experimental value. This contradition is resolved if one realizes that under the experimental conditions water is also reduced.

At any other less-negative potential the current will depend on the electrode kinetics. Now the condition that the reducible substance concentration becomes zero after the application of the potential step has to be replaced by a kinetics equation, which is a function of potential and the concentrations of surface reactant and product. No general solution is available except for the case when the reaction rate is linearly dependent on the concentrations of the surface reactant and product (23).

### 3.2 Description of the Model

The real porous electrode is formed by sintering nickel powder on a nickel grid to form a plaque. The plaque serves as the cathode, which is positioned in a cadmium nitrate solution with a pH value between 3 to 5. The passage of the current produces hydroxy ions which cause the cadmium to be deposited

into the porous pores. The transport phenomena associated with electrochemical reactions in a porous medium is very complicated. The approach here is to study the intrinsic reactions which take place inside the pores in a simple flat electrode. The plate electrode is submerged in a semi-infinite pool of electrolyte so that the mass transfer problem can be treated as a one-dimensional problem in the x-direction (perpendicular to the electrode surface). In the solution side, there is a thin double-charge layer near the electrode. The thickness of the double layer is on the order of 10 to 100 Å. It is too thin to be probed adequately, and the theory of the diffuse layer is a microscopic, rather than a macroscopic, phenomena. The mass transfer region to be considered here is thus located outside of this double layer.

The electrodeposition process operates on the principle that the hydroxy ion, which is generated by the reduction process, coprecipitates with the cadmium ion in the solution to form cadmium hydroxide crystalloid. The approach taken here to unravel the complicated sequence of reactions is to form a model which describes the transport processes and reactions. The model will first be used to analyze the experimental results obtained under the condition of no pricipitation reaction, by using an electrolytic solution which is free of cadmium ions. The heterogeneous reduction reaction will be determined. The transport and reaction

problems will then be examined in the case when the solution contains cadmium ions. The rate of the precipitation reaction will then be determined by matching the model's prediction and the experimental results.

## 3.3 Formulation of Transport Process Equations

Three ionic species to be considered in the electrochemical system are  $NO_3^-$ ,  $OH^-$  and  $Cd^{+2}$  ions. In the absence of migration and convection, the flux of each species is expressed as (24):

$$N_i = -D_i \frac{\partial C_i}{\partial x}$$
,  $i=1,2,3$ , (10)

where  $N_i$  is the flux of species i (moles/cm<sup>2</sup>-sec),  $D_i$  is the diffusion coefficient of species i (cm<sup>2</sup>/sec),  $C_i$  is the concentration of species i (moles/cm<sup>3</sup>), which is a function of both x and t, and i=1,2,3 corresponding to  $NO_3^-$ ,  $OH^-$  and  $Cd^{+2}$  ions.

The equation of continuity of each species is (24):

$$\frac{\partial C_{i}}{\partial t} = -\frac{d N_{i}}{d t} + R_{i}, \quad i=1,2,3,$$
 (11)

where  $R_i$  is the rate of production of species i (moles/cm<sup>3</sup>-sec) by precipitation reaction, which occurs

only in the presence of cadmium ions.

Substitution of equation (10) into (11) gives

$$\frac{\partial c_i}{\partial t} = Di \frac{\partial^2 c_i}{\partial x^2} + Ri , \quad i=1,2,3$$
 (12)

It is assumed that the precipitation reaction (3) can be treated as a homogeneous reaction and is linearly proportional to the degree of supersaturation. Therefore, the consumption rate of cadmium ion due to this reaction is:

$$R_3 = -k \left[ c_3 - \frac{Ksp}{(c_2)^2} \right]$$
 (13)

where k is the homogeneous reaction rate constant (sec  $^{-1}$ ), Ksp is the solubility constant of Cd(OH)<sub>2</sub>

and has the value of  $2x10^{-23}$  (moles<sup>3</sup>/cm<sup>9</sup>)<sup>(25)</sup>. By the stoichiometric relation of equation (3), the consumption rate of hydroxy ion due to the same reaction is:

$$R_2 = 2 R_3 = -2 k \left[ C_3 - \frac{K \epsilon p}{(C_2)^2} \right].$$
 (14)

Substitution of equations (13) and (14) into equation (12) leads to the following two differential equations:

$$\frac{3^{C_2}}{3^{t}} = D_2 \frac{3^{C_2}}{3^{x^2}} - 2 k \left[ c_3 - \frac{\text{Ksp}}{(c_2)^2} \right], \qquad (15)$$

For  $NO_3^-$  ion,

$$R_1 = 0.$$

Equation (12) for  $NO_3^-$  ion may be reduced to :

$$\frac{\partial C_1}{\partial t} = D_1 \frac{\partial^2 C_1}{\partial x^2} \qquad (17)$$

Only two of the three differential equations need to be solved for the concentration profiles, due to the electroneutrality condition (24):

$$2C_3 - C_1 - C_2 = 0$$
 (18)

Substitution of equation (18) into equation (15) gives:

$$\frac{\partial^{C}_{2}}{\partial t} = D_{2} \frac{\partial^{2}_{2}}{\partial x^{2}} - 2k \left[ \frac{1}{2} (C_{1} + C_{2}) - \frac{K_{sp}}{(C_{2})^{2}} \right].$$
 (19)

Equations (17) and (19) are solved simultaneously to obtain the concentration profiles of  ${\rm C_1}$  and  ${\rm C_2}$ , i.e.,  ${\rm NO_3^-}$  and  ${\rm OH^-}$  ions. The  ${\rm C_d^{+2}}$  profile can then be obtained by equation (18) from the known profiles of  ${\rm C_1}$  and  ${\rm C_2}$ .

A set of differential equations, which are simpler

than equations (17) and (19), are obtained when the electrolyte contains no cadmium ion. In the absence of cadmium ion, the precipitation reaction (3) can not occur; thus,  $R_i$  terms are all equal to zero. Equation (12) is then reduced to:

$$\frac{\partial^{C_i}}{\partial t} = D_i \frac{\partial^{2C_i}}{\partial x^2}, \quad i=1,2 , \qquad (20)$$

in which i=1,2 corresponds to  $NO_3^-$  and  $OH^-$  ions.

Equation (20) is written for  $C_1$  and  $C_2$ :

$$\frac{\partial^{C}_{1}}{\partial^{t}} = D_{1} \frac{\partial^{2}_{C_{1}}}{\partial x^{2}} \qquad (21)$$

$$\frac{\partial c_2}{\partial t} = D_2 \frac{\partial^2 c_2}{\partial x^2} \qquad (22)$$

The other condition, the concentrations of various ions at the electrode/electrolyte interface after the start of the current flow, has to be described by the electrode kinetics of the reduction reaction of  $NO_3^-$  ions.

### 3.4 Electrode Kinetics

The possible reduction reactions are numerous, as shown in equation (2). Since in each reaction, OH ion is generated, we will represent the production of OH.

ions as the following electrochemical reaction:

$$2H_2O + NO_3 + 2e^- \longrightarrow HNO_2 + 3OH^-.$$
 (23)

Because there are two electrons involved in the reaction, it is likely not an elementary step. Let's assume the reaction comprises two elementary steps, each step involving the transfer of one electron, and a dissociation reaction:

$$NO_3^- + H_2O^- + e^- \xrightarrow{K_{c1}} NO_2^- + (CH)_2^-$$
 (slow), (24a)

$$(OH)_{2}^{2} + e^{-}$$
  $K_{c2}$   $2OH^{-}$  (fast), (24c)

$$NO_2^- + H_2O \xrightarrow{K_d} HNO_2 + OH^-$$
 (fast), (25)

where  $K_{c1}$  and  $K_{c2}$  are cathodic reaction constants, and  $K_{a1}$  and  $K_{a2}$  are anodic reaction constants, respectively.  $K_{d}$  is the dissociation reaction constant.  $(OH)_{2}^{-}$  ion is an unstable intermediate ion which immediately enters the next reaction (24b). The rates of these elementary steps should always be proportional to each other. For the elementary steps listed above, reaction (24b) should occur once every time reaction (24a) occurs.

Let  $I_1$  and  $I_2$  denote the cathodic current densities of reactions (24a) and (24b), and  $r_1$  and  $r_2$  denote the reaction rates of reactions (24a) and (24b), respectively.

Then, the relationship between  $r_1$ ,  $I_1$  and surface ion concentrations of  $NO_3^-$ ,  $(CH)_2^-$ , which appear in elementary step (24a), may be written as (26):

$$r_{1} = \frac{I_{1}}{nF} = \frac{I_{1}}{F} \qquad (n=1)$$

$$= K_{a1} \left[ C_{NC_{2}}^{O} - \left[ C_{(OH)_{2}}^{O} \right] \exp \left[ \frac{(1-\beta_{I})F}{RT} \right] \right]$$

$$-K_{c1} \left[ C_{NO_{3}}^{O} - \left[ C_{H_{2}O}^{O} \right] \exp \left[ -\frac{\beta_{I}F}{RT} \right] \right]. \qquad (26)$$

Similarly, for reaction (24b), one has:

$$r_{2} = \frac{I_{2}}{nF} = \frac{I_{2}}{F} \qquad (n=1)$$

$$= K_{a2} \left[ C_{OH}^{o} - \right]^{2} \exp \left[ \frac{(1-\beta_{2})F}{RT} V \right]$$

$$-K_{c2} \left[ C_{OH}^{o} \right]^{2} \exp \left[ -\frac{\beta_{2}F}{RT} V \right], \qquad (27)$$

where  $\beta$ , and  $\beta_2$  are symmetry factors representing the fractions of applied potential V, which promotes the cathodic reaction.  $C_{NO_3}^0$ ,  $C_{(OH)_2}^0$  and  $C_{OH}^0$  are the surface ion concentrations of  $NO_3^0$ ,  $(OH)_2^0$  and  $OH^0$  on the electrode surface.

Since reactions (24a) and (24b) occur at the same rate, we have:

$$I = I_1 + I_2 = 2I_2 = 2I_1$$
,

where I is overall current density. It is further assumed that reaction (24b) is fast, and is essentially in equilibrium. From equation (27),

$$C_{(OH)_{2}}^{\circ} = \frac{K_{a2} \left[C_{OH}^{\circ} - \right]^{2} \exp\left[\frac{(1 - \beta_{2})F}{RT}V\right]}{K_{c2} \exp\left[-\frac{\beta_{2}F}{RT}V\right]}$$
(28)

and 
$$\frac{I_1}{F} = \frac{I}{2F} = r = \text{overall reaction rate.}$$
 (29)

Substituting equation (28) into equation (26) and combining equation (29) gives:

$$\frac{I}{2F} = r = \frac{K_{a1}K_{a2}}{K_{c2}} \left[ C_{NO_2}^{\circ} \right] \left[ C_{OH}^{\circ} \right]^2 \exp \left[ \frac{(2-\beta_I)F}{RT} V \right]$$

$$- K_{c1} \left[ C_{NO_3}^{\circ} \right] \left[ C_{H_2O}^{\circ} \right] \exp \left[ -\frac{\beta_I F}{RT} V \right]$$
(30)

From reaction (25) one may write

$$K^{q} = \frac{\left[\binom{c_0^{NO^{-1}}}{\binom{c_0^{NO^{-1}}}}}}}}$$

Substitution of the above expression into equation (30) leads to:

$$\frac{I}{2F} = r = \frac{K_{a1}K_{a2}}{K_{c2}K_d} \frac{\left[C_{HNO_2}^{\circ}\right]\left[C_{OH}^{\circ}\right]^3}{\left[C_{H_2O}^{\circ}\right]} \exp\left[\frac{(2-\beta_i)F}{RT}V\right] - K_{c1}\left[C_{NO_3}^{\circ}\right]\left[C_{H_2O}^{\circ}\right] \exp\left[-\frac{\beta_iF}{RT}V\right].$$
(31)

This is an overall expression of the relationship among the current density, surface concentrations of ions involved in the reaction (23) and applied potential. When the applied potential is kept constant and the surface concentrations of  $\rm H_2O$  and  $\rm HNO_2$  are almost constant, equation (31) is simplified to:

$$\frac{I}{2F} = r = K_{2} \left[ C_{OH}^{o} - \right]^{3} - K_{1} \left[ C_{NO_{3}}^{o} \right], \qquad (31a)$$
where  $K_{2} = \frac{K_{a1}K_{a2}}{K_{c2}K_{d}} \frac{\left[ C_{HNO_{2}}^{o} \right]}{\left[ C_{H_{2}O}^{o} \right]} \exp \left[ \frac{(2 - \beta_{I})F}{RT} V \right],$ 

$$K_{1} = K_{c1} \left[ C_{H_{2}O}^{o} \right] \exp \left[ - \frac{\beta_{I}F}{RT} V \right].$$

One can see from equation (31a) that the reaction is third order with respect to  $\mathrm{CH}^-$  ion and first order with respect to  $\mathrm{NO}_3^-$  ion. Equation (31a) will be used as one of our boundary conditions to be discussed in the next section.

## 3.5 Initial and Boundary Conditions

For both cases, i.e., electrolyte containing cadmium

ions and electrolyte containing no cadmium ions, two initial and four boundary conditions are needed to solve the differential equations (17) and (19) or (21) and (22).

At t=0, the concentration of each ion is equal to its bulk value at each point along the x-direction. The initial conditions are as follows:

1. at t=0, 
$$C_1 = C_1^b$$
 for all x,

2. at t=0, 
$$C_2 = C_2^{b}$$
 for all x,

where the superscript "b" denotes the bulk condition.

The first boundary condition is the consequence of the fact that the flux at the interface has to be equal to the rate of heterogeneous electrode reaction, i.e.:

$$\left[D_{1} \frac{\partial^{C}_{1}}{\partial x}\right]_{x=0} = K_{2} \left[C_{2}^{\circ}\right]^{3} - K_{1} \left[C_{1}^{\circ}\right], \qquad (32)$$

where superscript "o" denotes the surface condition. To satisfy the stoichiometric relation of equation (23), one has, at x=0:

$$3 \left[ -D_1 \frac{\partial^2 1}{\partial x} \right]_{x=0} = \left[ D_2 \frac{\partial^2 2}{\partial x} \right]_{x=0} . \tag{33}$$

This is the second boundary condition. The other two boundary conditions are:

3. at 
$$x = \infty$$
,  $C_1 = C_1^b$ ,  
4. at  $x = \infty$ ,  $C_2 = C_2^b$ .

That is, the concentrations far away from the electrode/ electrolyte interface do not change.

The flux in equation (32) is proportional to the current density as a function of time:

$$I = -2FD_1 \left[ \frac{\partial^C 1}{\partial x} \right]_{x=0}$$
 (34)

#### CHAPTER 4

#### EXPERIMENTAL WORKS

A potential-step was generated from a function generator and was applied to the working electrode/electrolyte interface in the electrochemical cell. The cathodic current was thus sampled and stored in memory at a constant time interval by a microcomputer. The resulting current/time transient was then plotted by a x-y recorder or printed out by a line printer by recalling these current data from the memory of the microcomputer.

### 4.1 The Electrochemical Cell

The current transient under a potential step condition was obtained in a three-electrode cell. The cell and electrodes configuration is shown in Figure 1. The working electrode was a nickel microelectrode. It was made of a nickel wire which was pressure-fitted into a teflon cylinder. The flat, exposed surface was 0.013 cm<sup>2</sup>. A saturated calomel electrode (SCE) and a cadmium bar were used as the reference and the counter electrodes, respectively.

The cell was filled with electrolyte of either

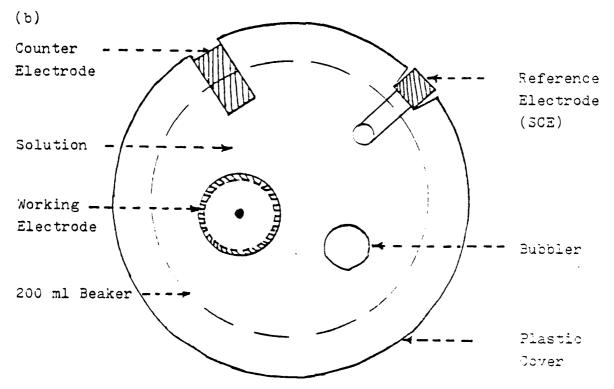

Figure 1. The Electrochemical Cell: (a) Side View, (b) Top View.

cadmium nitrate solution or potassium nitrate solution.

The pH value of the solution was controlled. Potassium chloride was used as the supporting electrolyte. The electrolytic solution was not stirred during the experiment, so that the conditions of semi-infinite linear diffusion were maintained.

Two experimental parameters were varied:

- 1) the ion concentration of the solutions and
- 2) the magnitude of the potential-step applied to the interface.

## 4.2 The Instruments and Electrical Setup

The block diagram for the experiment setup is shown in Figure 2. The instruments shown in Figure 2 contain the following equipment:

a) A Princeton Applied Research (PAR) Model 173 Fotentiostat/
Galvanostat: In the experiment, the operating mode was set at CONTROL E., which means that the instrument functioned as a potentiostat. The current was measured while keeping the potential of the working electrode constant. This was accomplished by setting the counter electrode to the required level so that the working electrode potential was at a programmed potential with respect to the reference electrode. The instrument is provided with a Model 176 Current-to-Voltage Converter which is the "basic" plug-in

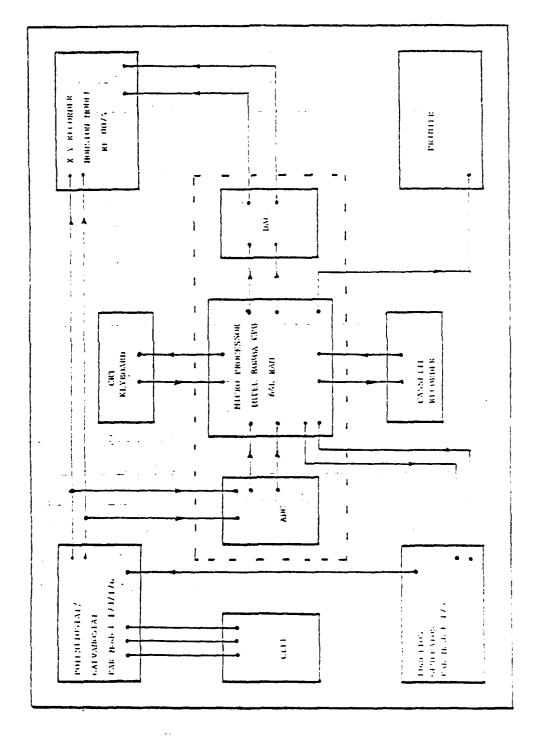

Figure .. Block Diagram for the Determination of the Current vs Time Relation.

module. The M 176 provides a do voltage output which is proportional to the current. The cell current can be either displayed on the panel, by a x-y recorder, or monitored by the microcomputer. Connection to the cell was made through the external cable. The counter electrode was connected to the red clip, the working electrode to the green clip and the reference electrode to the Electrometer Probe which has a very high impedance, thereby insuring us that the current was flowing to the reference electrode.

- b) A PAR Model 175 Function Generator: This is a programmable waveform generator which has two operating modes, SWEEP and PULSE. The former generates a sequence of triangular waves, while the latter generates a sequence of step function. For the potential step experiment, the operating mode was set at PULSE mode and the pulse width selector at STEP position. The magnitude of the step function was set by the setting of the B potential (upper limit) in the POTENTIAL section on the front panel of this instrument.
- c) An Intel CPU 8080A Bases Microcomputer (c4K RAM): The micro-computer was the central part of the experimental setup.

  The functions of the microcomputer in the experiment were:
  - (1) to trigger the Function-Generator which activated the potential step presented earlier.
  - (2) to sample the current outputs from the M 175 Converter and store them in the memory.
  - (3) to convert these digital data back into analog signals

and then plot them on the x-y recorder.

- (4) to print the digital data on the line printer.
- (5) to store these digital data in the tapes.

  The peripheral equipment of the microcomputer include a

  CRT (TV screen), the keyboard, a cassette recorder and a

  line printer.
- d) A Houston Model RE 0074 x-y Recorder: The Recorder receives the analog outputs from the DAC (Digital-Analog Converter) and plots them on the graph paper.

### 4.3 The Computer Program

A computer program written in BASIC language was used to carry out the experiment. The program consists of a main program and a machine-language subroutine called "MUG". This subroutine includes an execution statement which generates a trigger signal to activate the Function Generator. A potential step was then immediately applied to the working electrode, and thereafter the computer started to sample and store the current output at a fixed time interval. The analog signal was converted into a digital datum by a 12 bits ADC (Analog-Digital Converter) and then stored in the memory. When the number of samples reached a preset value, the sampling routine was terminated. The digital signals stored in the memory were binary numbers. These data were converted into decimal numbers and then converted into analog signals, and finally plotted on the x-y recorder and

printed on the line printer. This was executed by the main program. The main program and the "MUG" subroutine are presented fully in Appendix A1 and A2.

## 4.4 Experimental Conditions and Procedures

In the experiment, the initial pH value of the electrolyte was maintained at 3.0, which was the condition used in the actual electrochemical impregnation process. This was accomplished by titrating the electrolytic solution with a concentrated HCl solution. The concentrations of nitrate ion used were 0.005M, 0.0025M and 0.00125M prepared from either the KNO3 or Cd(NO3) solution. The cadmium ion concentrations were 0.0025M, 0.00125M and 0.000625M. All the electrolytic solutions contained 0.5M KCl as the supporting electrolyte.

It was found later that the electrolysis of water made significant contribution to the total current, because the current obtained was significantly higher than the limiting current. In order to obtain the current due only to the reduction of nitrate ions, several runs with solutions which contained no nitrate ion were conducted. The solutions used for this purpose were either water or 0.0025M CdCl<sub>2</sub> solution. Both solutions contained 0.5M KCl as the supporting electrolyte. This current was subtracted from the current obtained in the presence of

nitrate ions in the solution. The resulting current is the faradic current of the reduction of nitrate ions.

The magnitudes of the potential-step used in this study were -0.40V, -0.60V and -0.80V versus the equilibrium potential which was at approximately -0.354V vs SCE.

The experimental procedures are listed blow:

- (1) The electrical circuit was set up as shown in Figure 2, except that the cell was disconnected from the Potentiostat/ Galvanostat by setting the cell selector on the instrument to the OFF position. A proper current range was then chosen from the Current Range Switch to make sure that the current output would not be overloaded. The Function Generator was initialized by depressing the INITIAL control pushbuttom. The initial potential was set at zero volts.
- (2) A known volume of electrolytic solution and an equal volume of supporting electrolyte, KCl, were added to the cell and titrated with HCl solution to a pH value of 3.0. The solution was then deaerated by bubbling purified nitrogen through the stirred solution for about ten minutes. The gas continued to pass above the solution during the experiment.
- (3) After the working electrode surface was polished by a 3/0 alumina paper, it was rinsed thoroughly with distilled

and deionized water, and then was positioned in the cell. The electrodes (the working electrode, counter electrode and reference electrode) were then connected to the Potentiostat/Galvanostat as described in section 4.3. After the electrodes were correctly connected, the cell selector was switched to the EXTERNAL CELL position. The rest potential of the solution could be determined by turning the knob in the APPLIED POTENTIAL/CURRENT section of the front-panel of the Potentiostat/Galvanostat so that the current reading displyed on the front panel meter was zero. The applied potential was then the rest potential.

- (4) The upper limit (B potential) on the Function Generator was set. The value of the B potential plus the rest potential was the total potential applied to the electrochemical cell.
- (5) The experiment was initiated by running the computer program. The current/time data were stored in the computer's memory and then the results were converted to line printer output.

### 4.5 Experimental Results

Two sets, a total of twenty-two runs, were made. The first set of runs was conducted in solutions which contained no cadmium ion. The second set of runs was made in solutions

which contained cadmium ions. For each set of runs, blank runs were made in the solutions without the presence of nitrate ion for the purpose of determining the background current due to the water decomposition reaction. The solution for blank runs for the first set was water, while the solution for blank runs for the second set was made by using the 0.0025M CdCl<sub>2</sub> solution.

The current-density-vs.-time data printed by the H 14 Line Printer are shown in Table B.1 through Table B.22 in appendix B. The measured current was converted to the current density which appears in those tables. This is calculated by dividing the current by the electrode surface area 0.013cm<sup>2</sup>.

Tables B.1 through B.9 are the first data set which used potassium nitrate as the electrolytic solution, while Tables B.10 through B.12 are the background currents of water used to subtract from the first data set.

Tables 3.13 through 3.21 are the second data set which used cadmium nitrate as the electrolytic solution, while Table 3.22 is the background current of water in the presence of cadmium ions.

A series of current-density-vs.-time curves with various

electrolytic solution concentrations and applied overpotentials are shown in Figures 3 through 6. In these figures, the current due to the electrolysis of water has been eliminited by using the routine tabulated in Table 1.

Figures 3 through 5 are the current-density-vs.-time curves obtained in the solutions which did not contain cadmium ion. Figure 3 shows the current-density-vs.-time curves obtained in a solution containing 0.005M nitrate ion and at potentials -0.40V, -0.60V and -0.80V from the equilibrium potential. Figure 4 shows the current-density-vs.-time curves obtained in a solution containing 0.0025M nitrate ion, and at potentials -0.40V, -0.60V and -0.807 from the equilibrium potential. Figure 5 shows the current-density-vs.-time curves obtained in a solution containing 0.00125M nitrate ion at -0.40V, -0.60V and -0.80V from the equilibrium potential. Due to the lack of blank runs with 0.00125M and 0.000625M cadmium ion concentrations and -0.60V and -0.80V from the equilibrium potential, only one current-density-vs.-time curve was obtained with 0.005M nitrate ion and 0.0025M cadmium ion concentration at the potential of -0.40V from the equilibrium potential. This is shown in Figure 6.

## 4.6 Discussion of Experimental Results

Some characteristics can be seen from the curves shown in Figures 3 through 6.

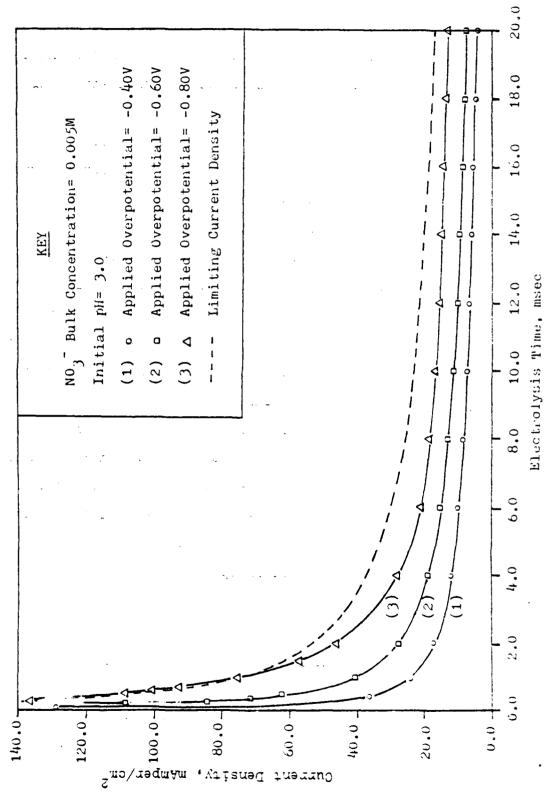

Figure 3: Current-Density-vs.-Time Curves in the Case of Electrolyte Containing No Cadmium Ion.

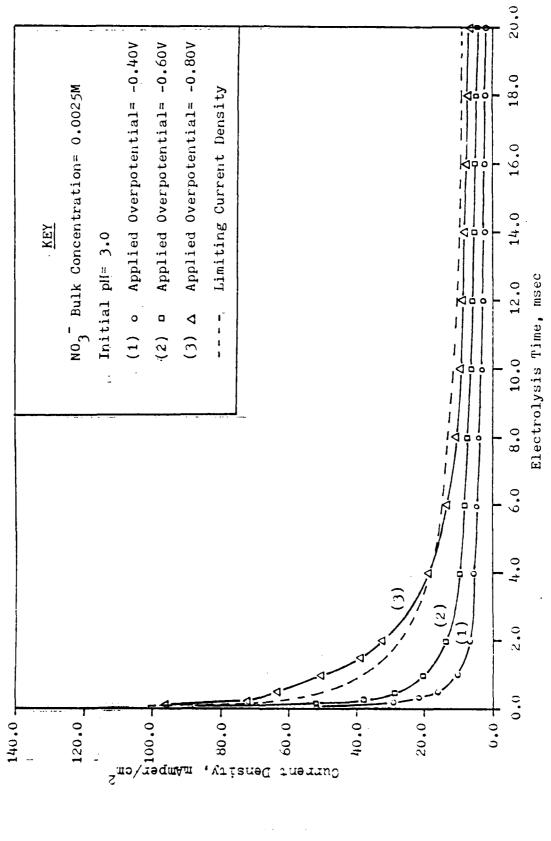

Figure 4: Current-Density-vs.-Time Curves in the Case of Electrolyte Containing No Cadmium Ion.

Firstly, the current density decays with time in a hyperbolic fashion. This is the result of depletion of the NO3 ions near the electrode surface. Theoretically, there is an initial sharp rise of current associated with double-layer charging (27), due to the application of a potential-step. This was not observed in the experiment, however, because the time for charging is usually very short as compared to the electrolysis time.

Secondly, the sharp current drops in the beginning indicate that very sharp concentration gradients are established for the nitrate ions and the hydroxy ions as soon as the surface reaction (23) takes place. The concentration gradients are gradually decreased due to the diffusion layer extending in the direction of decreasing concentration gradients. The result is that the decay of the current density is not as fast as in the beginning.

The curves for the case of potential at -0.80V from the equilibrium potential and solutions containing 0.0025M and 0.00125M nitrate ion, as shown in the upper-most curves in Figures 4 and 5, respectively, are somewhat different from the others. These two curves do not follow the same trends as their lower potential counterparts. It is suggested that the reactant, nitrate ion, near the electrode surface, is used up in a very short time and another reaction must be taking place. This

behavior is the most pronounced as shown in the upper-most curve in Figure 5. A maximum current is observed at time equal to about 0.5 msec. This curve thus strongly supports our explanation that some other reaction is taking place at that time. On the other hand, the absence of this behavior in the curve for the case of 0.005M nitrate ion shown in the upper-most curve in Figure 3 suggests that the nitrate ion concentration near the electrode surface is not zero.

Two parameters were varied in the experiment, i.e., the concentration of the electrolyte solutions and the value of the potential from the equilibrium potential (rest potential). The changing of either the bulk concentration of the electrolyte solutions or the overpotential that is applied to the working electrode will change the value of the current density. For a given bulk concentration, the increase in the applied overpotential increases the electrochemical reaction rate on the electrode surface. The effect of the applied overpotential on the current density can also be observed in Figures 3 through 5. In each of these figures, a plot of the limiting current density-vs.-time curve is also shown. The limiting current density is calculated by equation (9) with the corresponding bulk concentration of the nitrate ion. Recall that the limiting current is defined as maximum current one can obtain as the applied overpotential is increased. The surface concentration of the reactant for the case of limiting current is, in fact,

zero at any time. After examining Figures 3 through 5, we find that, for the case of -0.80V, some of the values of current density exceed the limiting current density. This phenomenon becomes more significant when the bulk concentration of potassium nitrate is decreased. The reason for this phenomenon probably is that at the high applied overpotential, many reactions can subsequently be expected to take place. The maximum current appearing in the curve for the case of -0.80V is a result of this behavior.

When the applied overpotential is fixed, the heterogeneous reaction rate constants in both the cathodic and anodic directions,  $K_1$  and  $K_2$ , are fixed. The supply of the nitrate ions on the electrode surface comes only in the way of diffusion of the nitrate ions from the bulk solution. Increasing the bulk toncentration will increase the rate of nitrate ion supply to the electrode surface, thusly increasing the current density. Figures 7 through 9 show the effect of the bulk concentration of the electrolytic solution on the current density with fixed applied overpotential. From the three figures, we can see that the current density is approximately proportional to the bulk concentration of potassium nitrate, except for the case of -0.30v.

When electrolytic solution contains cadmium ions, a different set of results was obtained. The experimental current-density-vs.-time curve obtained in a 0.0025M

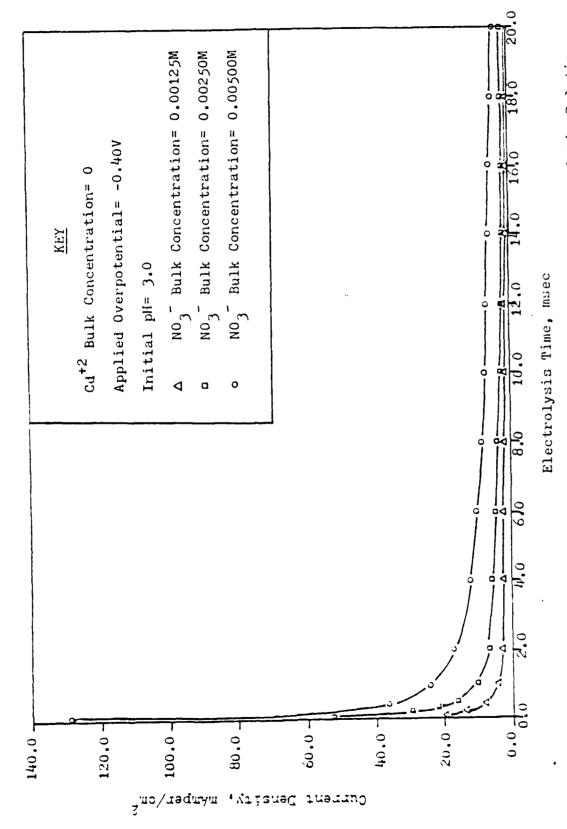

Figure 7: Effect of the Bulk Concentration of the Electrolytic Solution on the Current Density with Fixed Applied Overpotential.

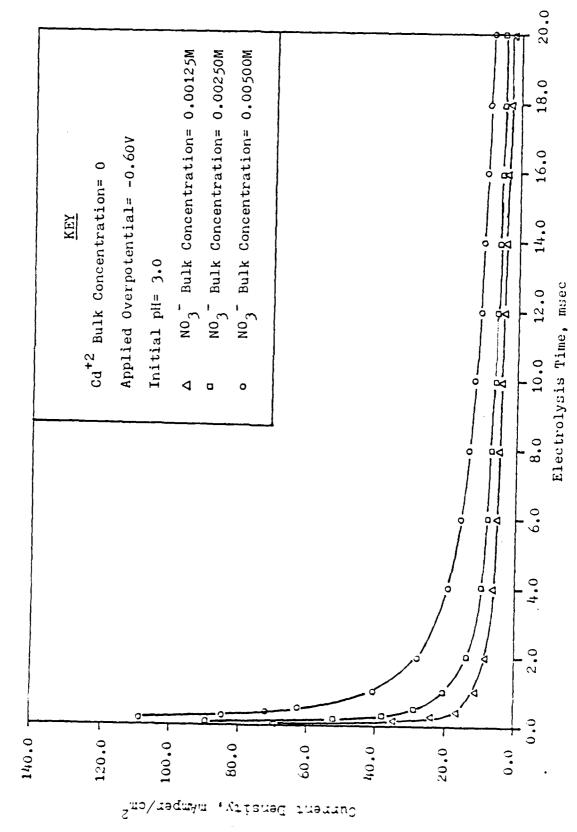

Figure 8, Effect of the Bulk Concentration of the Electrolytic Solution on the Current Density with Fixed Applied Overpotential

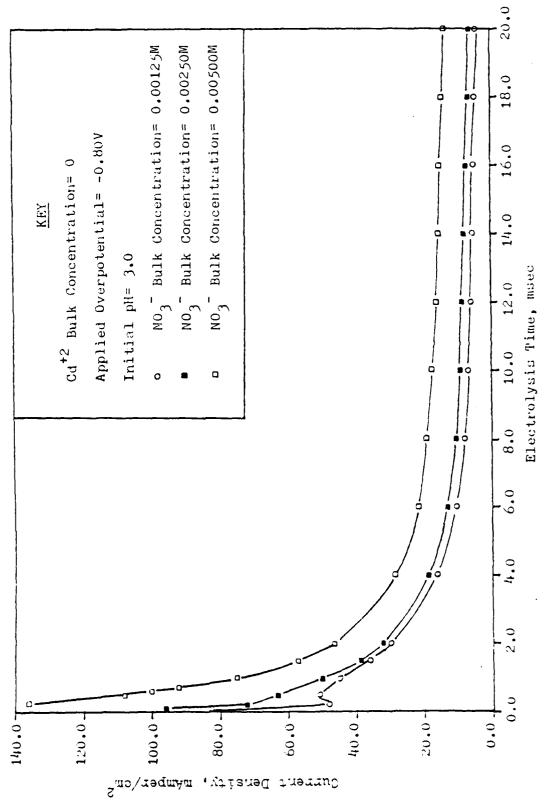

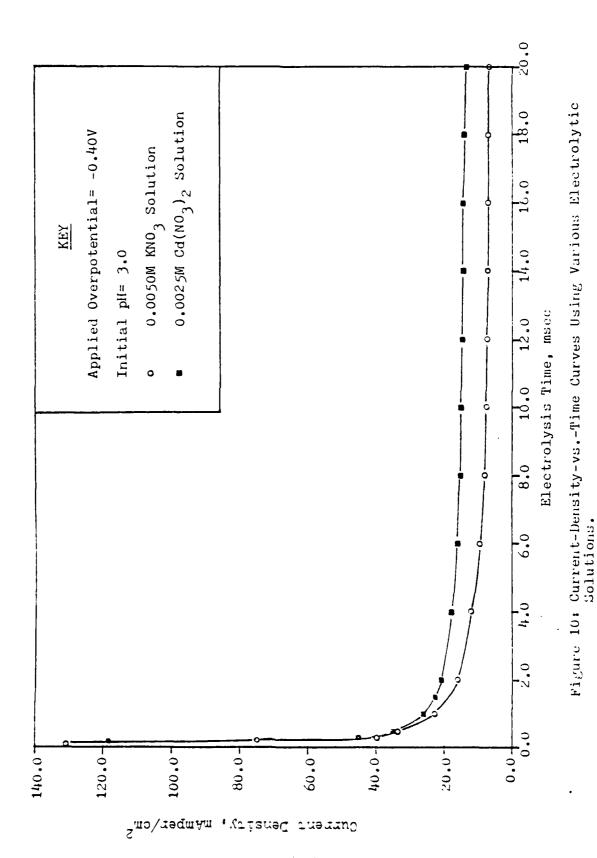

Figure 9: Effect of the Bulk Concentration of the Electrolytic Solution on the Current Density with Fixed Applied Overpotential.

 $Cd(NO_3)_2$  solution and at -0.40V applied overpotential is shown in Figure 6. In addition to the electrochemical reduction of the nitrate ions on the electrode surface, a precipitation reaction also takes place in the solution because the cadmium ions in the electrolytic solution can coprecipitate with the hydroxy ions produced by the electrochemical reaction on the electrode surface. The current density is expected to be greater than that when the cadmium ion is absent from the electrolytic solution. Figure 10 shows the current-densityvs.-time curves obtained in a 0.005M  $KNO_3$  solution and in a 0.0025M  $Cd(NO_3)_2$  solution. The applied overpotential is -0.407 for both cases. From the curves, one can see that the current density obtained in the 0.0025M  $Cd(NO_3)_2$  solution is larger than that obtained in a 0.005M  $\ensuremath{\mathrm{KNO}_3}$  solution. The reason for this is that the consumption of the hydroxy ions due to the precipitation reaction establishes a driving force to produce more hydroxy ions and thus promote the electrochemical reaction. Some interesting facts may be seen from the figure. Firstly, the difference between two current densities increases as time increases, finally reaching a constant difference; secondly, the rate of decrease of the current density with time is slower for the case of using  $Cd(NO_3)_2$  as the electrolytic solution. One may thus obtain a larger steady state current density using  $\mathrm{Cd}(\mathrm{NO}_3)_2$  as the electrolytic solution.

### CHAPTER 5

## NUMERICAL SOLUTIONS OF THE THEORETICAL MODEL

## 5.1 Orthogonal Collocation Method

There are many numerical techniques which can be used to solve the differential equations of the theoretical model presented earlier in Chapter 3.

Orthogonal collocation method was selected as the method of solution. The orthogonal collocation method requires very little implicit mathematics and results in a large savings in computer time over the common finite difference scheme such as the Crank-Nicholson method. A brief description of the orthogonal collocation method is presented in Appendix C.

### 5.2 Working Equations

## 5.2.1 <u>Dimensionless Form of the Differential Equations</u>

The orthogonal collocation method requires the region of solution to be restricted to the interval  $\{0,1\}$ . This is accomplished by normalizing the spatial variable by the parameter,  $\{0,1\}$ , the diffusion thickness,  $\{-x/6\}$ .

The concentration variables are also reduced to the dimensionless forms:

$$c_1^* = \frac{c_1}{c_1^b}$$
 ;  $c_2^* = \frac{c_2}{c_1^b}$ 

the dimensionless time is defined as:

$$\tau = \frac{D_2 t}{\delta^2}.$$

Substituting the above dimensionless variables into equations (17) and (19) and rearranging leads to the following dimensionless equations:

$$\frac{\partial C_1^*}{\partial \tau} = \left(\frac{D_1}{D_2}\right) \frac{\partial^2 C_1^*}{\partial \xi^2} \tag{35}$$

$$\frac{\partial^{c_{2}^{*}}}{\partial \tau} = \frac{\partial^{2}c_{2}^{*}}{\partial \xi^{2}} - 2K \left[\frac{1}{2}(c_{1}^{*} + c_{2}^{*}) - \frac{DKSD}{(c_{2}^{*})^{2}}\right]$$
(36)

where 
$$K = \frac{k \delta^2}{D_2}$$
 and  $DKsp = \frac{Ksp}{(C_1^0)^3}$ 

are the dimensionless homogeneous reaction rate constant and solubility product, respectively. Similarly, equations (21) and (22) become:

$$\frac{\partial c_1^*}{\partial \tau} = \left(\frac{D_1}{D_2}\right) \frac{\partial^2 c_1^*}{\partial \xi^2} \tag{37}$$

$$\frac{\partial^{c_2}^{*}}{\partial \tau} = \frac{\partial^{2}c_2^{*}}{\partial \xi^2} \tag{33}$$

The initial conditions are:

1. at 
$$r = 0$$
,  $C_1^* = 1$ , for all  $0 \le \xi \le 1$ ,  
2. at  $r = 0$ ,  $C_2^* = C_2^b/C_1^b$ , for all  $0 \le \xi \le 1$ .

The first two boundary conditions come from the dimensionless form of equations (32) and (33):

1. 
$$\left(\frac{D_{1} C_{1}^{b}}{\delta}\right) \left[\frac{\partial C_{1}^{*}}{\partial \xi}\right]_{\xi=0} + \left[K_{2} (C_{1}^{b})^{3} (C_{2}^{o*})^{3} - (K_{1}C_{1}^{b}) C_{1}^{o*}\right] = 0$$
,

2.  $3\left(\frac{D_{1}}{D_{2}}\right) \left[\frac{\partial C_{1}^{*}}{\partial \xi}\right]_{\xi=0} + \left[\frac{\partial C_{2}^{*}}{\partial \xi}\right]_{\xi=0} = 0$ .

The other two boundary conditions are:

3. at 
$$\S = 1$$
,  $C_1^* = 1$ , for  $\Upsilon > 0$ ,  
4. at  $\S = 1$ ,  $C_2^* = C_2^b/C_1^b$ , for  $\Upsilon > 0$ .

### 5.2.2 Discretized Equations

The solution is approximated by a (N+2)th-order Legendre polynomial which satisfies the differential equations and boundary conditions exactly at N+2 points. Those points are chosen to be zeros of the Legendre polynomial of degree N over the interval (0,1) and with the boundary points 0 and 1. Discretizing the spatial derivatives at those points leads to

the following set of first-order ordinary differential equations:

$$\frac{dC_{1}^{*}}{d\tau} \bigg|_{\xi_{i}} = (\frac{D_{1}}{D_{2}}) \left[ \sum_{j=1}^{N+2} B_{i,j} C_{1}^{*}(\xi_{j}, \tau) \right]$$

$$i = 2, \dots, N+1, \qquad (39)$$

$$\frac{dc_{2}^{*}}{d\tau} = \sum_{j=1}^{N+2} B_{i,j} c_{2}^{*}(\xi_{j}, \tau) - 2K \left(\frac{1}{2}(c_{1}^{*}(\xi_{i}, \tau) + c_{2}^{*}(\xi_{i}, \tau) - \frac{DKsp}{c_{2}^{*}(\xi_{i}, \tau)^{2}}\right)$$

$$i = 2, \dots, N+1,$$
 (40)

where  $\xi_i$ ,  $i=2,\ldots$  N+1 are the N interior collocation points which while  $\xi_1$  and  $\xi_{N+2}$  are exterior collocation points which correspond to the boundary points at  $\xi=0$  and  $\xi=1$ , respectively, and  $0=\xi_1<\xi_i<\xi_{N+2}=1$ ,  $i=2,\ldots$  N+1.  $B_{i,j}$  is a (N+2) by (N+2) coefficient matrix which comes from the discretization of the second derivative  $(\partial^2 C_1^*/\partial \xi^2)$  or  $\partial^2 C_2^*/\partial \xi^2$ ) at each collocation point. A detailed explanation of matrix B is shown in Appendix C.  $C_1^*(\xi_j,\tau)$  and  $C_2^*(\xi_j,\tau)$  are the concentrations of species 1 and 2, respectively, at time  $\tau$  and position  $\xi_i$ .

The discretized equations from equations (37) and (38) are:

$$\frac{dC_{1}^{*}}{d\mathcal{T}} = \left(\frac{D_{1}}{D_{2}}\right) \left[\sum_{j=1}^{N+2} B_{i,j} C_{1}^{*}(\xi_{j}, \mathcal{T})\right], i = 2, ... N+1, (41)$$

and

$$\frac{dC_2}{d\tau} \Big|_{\xi_i} = \sum_{j=1}^{N+2} B_{i,j} C_2^*(\xi_j,\tau), i=2,...N+1.$$
 (42)

The other four equations are obtained by requiring that the approximation polynomial satisfies the boundary conditions:

$$\left( \begin{array}{c} \frac{D_{1}C_{1}^{b}}{\delta} \right) \left( \sum_{j=1}^{N+2} A_{1,j} C_{1}^{*}(\xi_{j},\tau) \right) + \left( K_{2}(C_{1}^{b})^{3} C_{2}^{*}(\xi_{1},\tau)^{3} - (K_{1}C_{1}^{b}) C_{1}^{*}(\xi_{1},\tau) \right) = 0, \text{ for all } \tau > 0,$$

$$(43)$$

$$3(\frac{D_1}{D_2})\left(\sum_{j=1}^{N+2} A_{1,j} C_1^*(\xi_j,\tau)\right) + \left(\sum_{j=1}^{N+2} A_{1,j} C_2^*(\xi_j,\tau)\right) = 0,$$

$$C_1^*(\xi_{N+2}, \tau) = 1,$$
 for all  $\tau > 0$ , (-5)

$$C_2^*(\xi_{N+2}, \tau) = C_2^b/C_1^b$$
, for all  $\tau > 0$ , (46)

where  $A_{i,j}$  is an element of another (N+2) by (N+2) coefficient matrix which comes from the discretization of the first-order derivative ( $C_1^*/O_5$  or  $C_2^*/O_5$ ) at each collocation points. Since only boundary conditions 1 and 2 (equations (43) and (44)) require the evaluation of the first-order derivative at  $\xi_1$ =0, only the first row of the matrix A, i.e.,  $A_1$ , is used here.

The initial conditions for both cases are the same: I.C.'s

1. at 
$$\gamma = 0$$
,  $C_1^*(\xi_i, \gamma) = 1$ ,  $i = 1, ..., N+2$ ,  
2. at  $\gamma = 0$ ,  $C_2^*(\xi_i, \gamma) = C_2^b/C_1^b$ ,  $i = 1, ..., N+2$ .

## 5.2.3 Calculation of Current Density

The current density is related to the flux of the nitrate ion at the electrode surface by equation (34). The discretized and dimensionless form of equation (34) is:

$$I = -\left[\frac{2FD_{1}C_{1}^{b}}{\delta}\right] \left[\frac{\partial C_{1}^{*}}{\partial \xi}\right]_{\xi=0}$$

$$= -\left[\frac{2FD_{1}C_{1}^{b}}{\delta}\right] \left[\sum_{j=1}^{N+2} A_{1,j} C_{1}^{*}(\xi_{j}, \tau)\right]. \tag{47}$$

# 5.3 The Introduction of a Spline Point to the Discretized Equations

The diffusion thickness introduced in the derivation of the dimensionless form in the previous section can be justified by selecting the total electrolysis time such that diffusion effects are negligible at x=8 during that period. At the beginning of the electrolysis, the diffusion thickness selected according to the total electrolysis time is too large. This leads to a concentration profile which is flat in most of the interval with a sharp drop in a very small region near  $\xi=0$ . This would require a large number of collocation points leading to a very stiff set of ordinary differential equations.

This difficulty can be overcome by the use of a method called spline collocation (28) based on the diffusion boundary concept. This method maintains a fixed low number of collocation points in the interval which is very small initially and will be increased as time increases to account for the thickening of the diffusion layer. In the regions outside this interval, the concentration is flat. As a matter of fact, the spline point can be located as close to the interface as to achieve any desired accuracy (28),

In order to be sure that the concentration gradient

at the spline point is zero, the concentration at the Nth collocation point, i.e., the last one before the spline point, is tested to assure that it is within a very small range of the bulk condition. At the time when such a test fails, the spline point is moved further into the solution.

Introducing a spline point,  $\xi_s$ ,  $0 < \xi_s < 1$ , a new variable,  $z = \xi / \xi_s$ , is introduced. The discretized equations we obtained for the case of solution containing cadmium ions are:

$$\frac{dC_{1}^{*}}{d\mathcal{T}}\Big|_{z_{1}^{*}} = (\frac{1}{\xi_{s}^{2}}) (\frac{D_{1}}{D_{2}}) \left[ \sum_{j=1}^{N+2} B_{i,j} C_{1}^{*}(z_{j}, \mathcal{T}) \right]$$

$$i=2,...N+1, \qquad (48)$$

and

$$\frac{dC_{2}^{*}}{d\tau}\Big|_{z_{\underline{i}}} = \left(\frac{1}{\xi_{s}^{2}}\right) \left[\sum_{j=1}^{N+2} \beta_{i,j} C_{2}^{*}(z_{j},\tau)\right] - 2K \left[\frac{1}{\xi}(C_{1}^{*}(z_{i},\tau)) + C_{2}^{*}(z_{i},\tau)\right] - \frac{2K\beta D}{C_{2}^{*}(z_{i},\tau)}\right]$$

$$= \frac{1}{\xi_{s}^{2}} \left[\sum_{j=1}^{N+2} \beta_{i,j} C_{2}^{*}(z_{j},\tau) - \frac{2K\beta D}{C_{2}^{*}(z_{i},\tau)}\right]$$

$$= \frac{1}{\xi_{s}^{2}} \left[\sum_{j=1}^{N+2} \beta_{i,j} C_{2}^{*}(z_{j},\tau)\right]$$

$$= \frac{1}{\xi_{s}^{2}} \left[\sum_{j=1}^{N+2} \beta_{i,j} C_{2}^{*}(z_{j},\tau)\right] - \frac{2K\beta D}{C_{2}^{*}(z_{i},\tau)}$$

For the case of solution containing no cadmium ion,

$$\frac{dC_{1}^{*}}{d\tau} \bigg|_{z_{1}} = \left(\frac{1}{\xi_{s}^{2}}\right) \left(\frac{D_{1}}{D_{2}}\right) \left[\sum_{j=1}^{N+2} B_{i,j} z_{1}^{*}(z_{j},\tau)\right]$$

$$i=2,...N+1, \qquad (50)$$

$$\frac{\mathrm{d}C_{1}^{*}}{\mathrm{d}\tau} \bigg|_{z_{1}} = \left(\frac{1}{\xi_{s}^{2}}\right) \left(\sum_{j=1}^{N+2} \beta_{1,j} C_{2}^{*}(z_{j},\tau)\right)$$

$$i=2,\dots,N+1. \tag{51}$$

Equations (43) through (46), which come from the four boundary conditions, become:

1. 
$$\left(\frac{1}{5}\right) \left(\frac{D_{1}c_{1}^{b}}{\delta}\right) \left(\sum_{j=1}^{N+2} A_{1,j}c_{1}^{*}(z_{j},\tau)\right) + \left[K_{2}(c_{1}^{b})^{3}c_{2}^{*}(z_{1},\tau)^{3}\right] - \left(K_{1}c_{1}^{b}\right)c_{1}^{*}(z_{1},\tau) = 0, \text{ for all } \tau > 0,$$
 (52)

2. 
$$3(\frac{D_1}{D_2})\left[\sum_{j=1}^{N+2} A_{1,j}C_1^*(z_j,\tau)\right] + \left[\sum_{j=1}^{N+2} A_{1,j}C_2^*(z_j,\tau)\right] = 0,$$

3. 
$$C_1^*(\xi_s, \tau) = C_1^*(z_{N+2}, \tau) = 1$$
, for all  $\tau > 0$ , (54)

4. 
$$C_2^*(\xi_s, \tau) = C_2^*(z_{N+2}, \tau) = C_2^b/C_1^b$$
, for all  $\tau > 0$ . (55)

The initial conditions become:

I.C.'s:

1. at 
$$\tau = 0$$
,  $C_1^*(z_i, \tau) = 1$ ,  $i=1,...N+2$ ,

2. at 
$$\tau = 0$$
,  $C_2^*(z_1, \tau) = C_2^b/C_1^b$ ,  $i=1,...N+2$ .

The current density should be changed to:

$$I = -\left[\frac{2FD_{1}C_{1}^{b}}{\delta}\right] \left[\frac{\partial C_{1}^{*}}{\partial \xi}\right]_{\xi=0}$$

$$= -\left(\frac{1}{\xi_{s}}\right) \left(\frac{2FD_{1}C_{1}^{b}}{\delta}\right) \left[\frac{\partial C_{1}^{*}}{\partial \xi}\right]_{z=0}$$

$$= -\left(\frac{1}{\xi_{s}}\right) \left(\frac{2FD_{1}C_{1}^{b}}{\delta}\right) \sum_{j=1}^{N+2} A_{1,j}C_{1}^{*}(z_{j}, \gamma). \quad (56)$$

### 5.4 Solution Procedures

For the case of a solution containing cadmium ions, equations (48), (49) and (52) through (55), with the initial conditions, are the working equations used to solve for the concentration profiles of  $NO_3^-$  and  $OH^-$  ions. The  $Cd^{+2}$  ion concentration is calculated by the electroneutrality condition in the solution:

$$C_3^*(z_1, \tau) = \frac{1}{2} \left[ C_1^*(z_1, \tau) + C_2^*(z_1, \tau) \right]$$
 (57)

For the case of a solution containing no cadmium ion, equations (50), (51) and (52) through (55) with the initial conditions, are the working equations.

Equation (56) is used to calculate the current density at each time  $\tau$  for both cases.

## 5.5 Computer Program Structure

The computer program for solving the discretized equations consists of a main program and 5 main subroutines. The first main subroutine evaluates the collocation points (roots) of the Jacobi polynomial of order N, as well as the firs and second derivatives of the polynomial at the roots. These derivatives are then used in a second main subroutine to calculate the discretization coefficient matrices A and B. The third main subroutine is used to perform a semi-implicit integration using Gear's routine (29). This subroutine calls 4 external subroutines. The first of these contains the explicit expressions (48) and (49) (or (50) and (51) in another case) for the discretized coupled first order differential equations containing the  $B_{i,j}$  terms; the second contains the Jacobian matrix for the same equation; the third performs the first stage of Gaussian elimination (30) of the Jacobian matrix; the Last performs the back substitution of Gaussian elimination

of the Jacobian matrix. The first external subroutine called by the integration subroutine also calls another subroutine coming from the IMSL package. This subroutine solves equations (52) and (53) simultaneously to give the surface concentrations of  $C_1^*$  and  $C_2^*$ . The IMSL subroutine calls another function which feeds the equations to be solved. Before writing the function,  $C_2^*(z_1, \boldsymbol{\tau})$  (surface concentration of  $C_2^*$ ) is solved in terms of  $C_1^*(z_1, \boldsymbol{\tau})$ , i=1,...N+2, and  $C_2^*(z_1, \boldsymbol{\tau})$ , i=1,...N+2, using equation (53), and then substitute into equation (52) to eliminate  $C_2^*(z_1, \boldsymbol{\tau})$ . Thus, only one equation which contains only one unknown,  $C_2^*(z_1, \boldsymbol{\tau})$ , is needed. Once we obtain  $C_1^*(z_1, \boldsymbol{\tau})$ ,  $C_2^*(z_1, \boldsymbol{\tau})$  can be calculated easily.

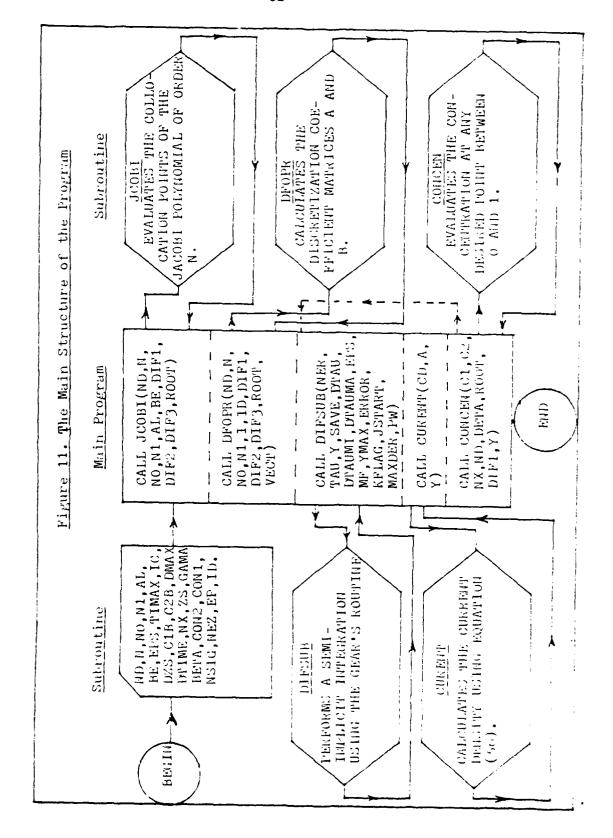

The Jacobian matrices for both cases can also be evaluated after substituting the expression of  $C_2^*(z_1, 7)$  into equations (48) and (49) (or (50) and (51) in another case). For the case of solution containing no cadmium ion, the Jacobian matrix is:

$$J_{\frac{1}{2},\frac{1}{3}} = \begin{bmatrix} \frac{D_1}{D_2} & \frac{1}{3} & \frac{1}{3$$

which is a 2N by 2N matrix. For the case of solution containing cadmium ions, the Jacobian matrix is the same except that the terms in the diagonal line of the third quadrant are all subtracted by K and the terms in the diagonal line of the fourth quadrant are all subracted by  $2K(\frac{1}{2}+(2DKsp/C_2^*(z_{1-N+1}, \mathcal{T})^3))$ .

The values obtained from the integration subroutine are then used in a fourth main subroutine to calculate the current density by equation (56). The last main subroutine is used to evaluate the concentration at any desired point between 0 and 1 by interpolation using the values at the collocation points.

The structure of the whole program is shown in Figure 11. Programs from both cases are listed in Appendix D. Programs herein were executed on an AMDAHL 470/V6 computer.

#### CHAPTER 6

### FITTING OF THE THEORETICAL MODEL WITH EXPERIMENTAL DATA

### 6.1 The Determination of the Electrochemical Reaction Kinetics Parameters

The unknown heterogeneous reaction rate constants which appear in equation (52) were determined from the current-density-vs.-time data obtained in a solution which did not contain cadmium ion. The differential equations (50) and (51) which describe the transport process were solved by computer to determine the rate constants. Comparing equation (31) with equation (31a), one can see that both  $K_1$  and  $K_2$  depend on the applied potential with exponential dependence. Thus,  $K_1$  and  $K_2$  should be constant when the applied potential is maintained at a constant value during the electrolysis.  $K_1$  and  $K_2$  were obtained by comparing the experimental data in the absence of cadmium ion in the electrolyte with the computer-calculated current density data.

The experimental current-density-vs.-time data

with the electrolyte containing 0.005M nitrate ions and the applied overpotential of -0.40V was first fitted to the computer-simulated data to obtain the  $K_1$  and  $K_2$  values. Due to the lack of information about the values of  $K_1$  and  $K_2$ , rough estimates of  $K_1$  and  $K_2$  were evaluated by substituting the applied potential V, which is equal to the value of the applied overpotential plus the rest potential, to equations (31) and (31a). The estimated values of  $K_1$  and  $K_2$  were increased or decreased until the computer-calculated current-density-vs.-time curve had the same shape as the same curve obtained experimentally. (Note, the background water decomposition current has been subtracted.)

After we obtained the right shape, the anodic reaction rate constant,  $K_2$ , was then fixed. By changing  $K_1$ , one can make the entire curve shift upward. Conversely, decreasing the  $K_1$  value will decrease the current density at each time point and thus shift the entire curve downward. A set of current-density-vs.—time curves with fixed  $K_2$  values and different values of  $K_1$  are plotted in Figure 12. The values of  $K_1$  and  $K_2$  when the concentration of nitrate ions is 0.005M and the applied overpotential is -0.40V was obtained

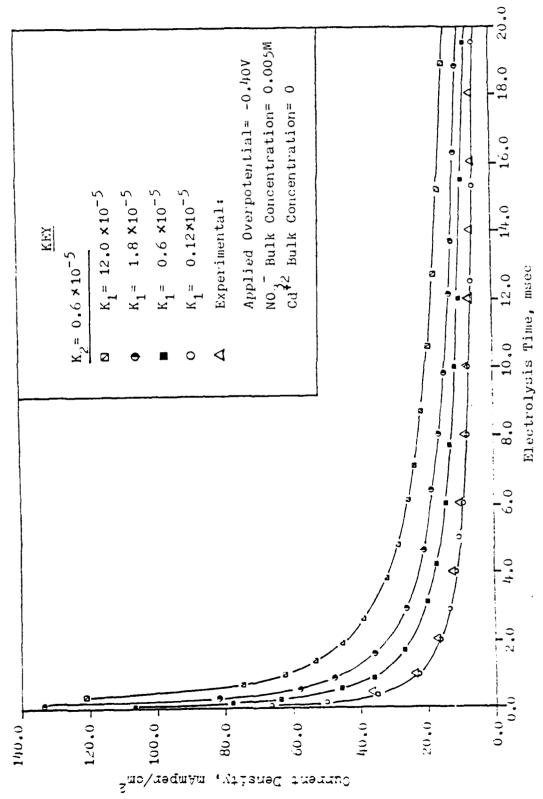

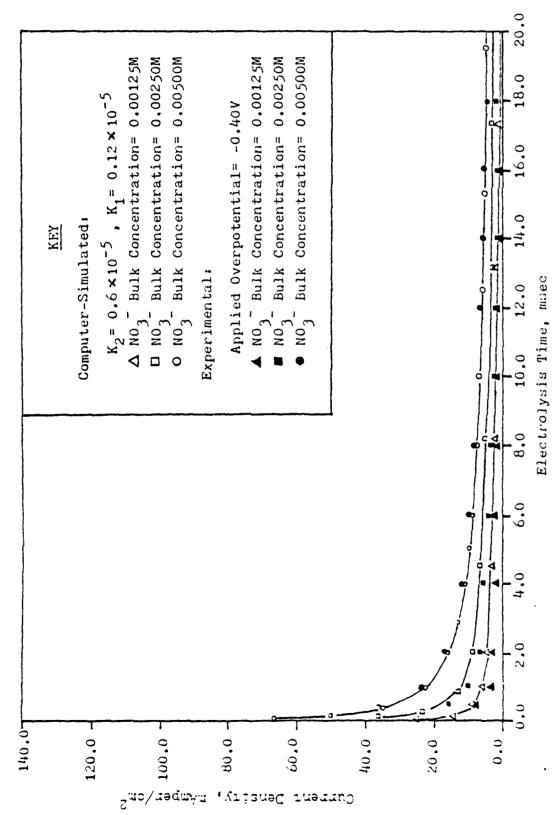

Figure 12: Computer-Simulated Current-Density-vs.-Time Curves with Fixed  $\rm K_2$  and Various  $\rm K_1^+ s.$ 

by interpolating the experimental curve between those curves in Figure 12. The values of  $K_1$  and  $K_2$  which achieved the best approximation of the experimental data are  $K_1 = 0.12 \times 10^{-5}$  and  $K_2 = 0.6 \times 10^{-5}$ , respectively.

These values were then used to predict the current-density-vs.-time curves at the other ion concentrations. Figure 13 shows the computer-simulated current density curves and experimental curves at various nitrate ion concentrations.

The values of  $K_1$  and  $K_2$  at the applied overpotential of -0.60V were different from those at -0.40V. The same procedure was used in evaluating the values of  $K_1$  and  $K_2$  at the condition of -0.60V. Figure 14 shows a set of calculated current-density-vs.-time curves with fixed  $K_2$  valued and different values of  $K_1$ . The value of  $K_1$  at the condition of -0.60V was then obtained in the same way as before. The values of  $K_1$  and  $K_2$  were determined to be 0.10  $\times 10^{-5}$  and 0.50  $\times 10^{-6}$ , respectively. These values were then used to predict the current-density-vs.-time curves at the other ion concentrations. Figure 15 shows the comparison of the predicted and experimental current-density-vs.-time curves.

The reaction rate constants at the applied overpo-

Curves with Various Nitrate Ion Bulk Concentrations in the Case of Electrolyte Containing No Cadmium Ion. Figure 13: Experimental and Computer-Simulated Current-Density-vs.-Time

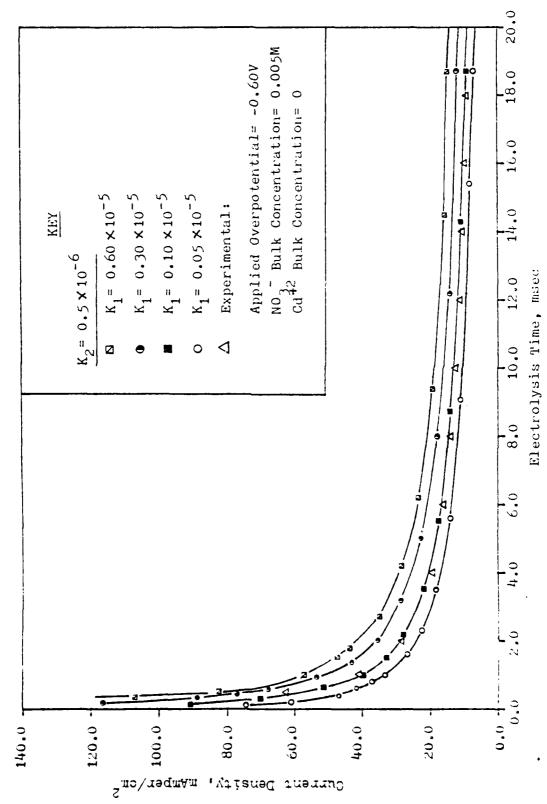

Figure 14: Computer-Simulated Current-Density-vs.-Time Curves with Fixed  $\rm K_2$  and Various  $\rm K_1^{+}s$ 

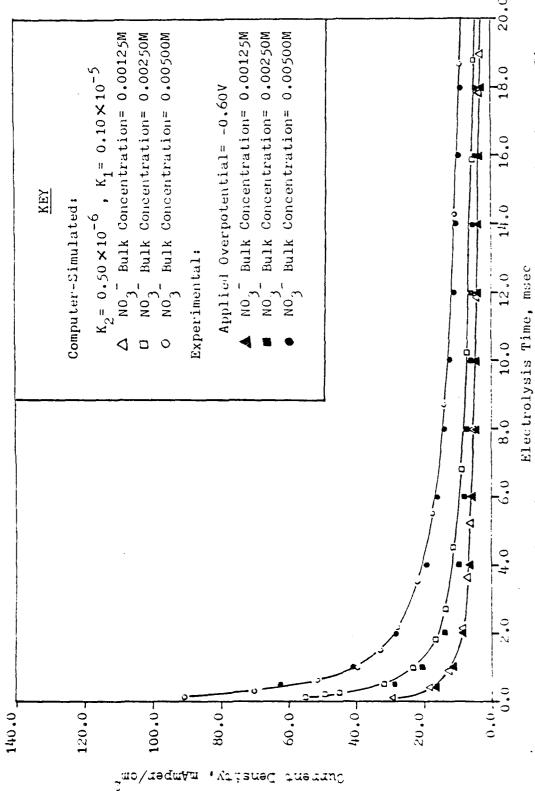

Figure 15: Experimental and Computer-Simulated Current-Density-vs.-Time Curves with Various Nitrate Ion Bulk Concentration in the Case of Electrolyte Containing No Cadmium Ion.

tential of -0.80V were not pursued. The reason, which was discussed previously, is that at this high applied overpotential more complicate sequences of reactions take place. This simple reaction expression can not describe the phenomena.

The heterogeneous rate expression so determined is believed to be a correct one. This claim is supported by the fact that the rate constants,  $K_1$  and  $K_2$ , are independent of the bulk concentration at a given potential. This is indeed the case as was shown in Figures 13 and 15.

# 6.2 The Determination of the Homogeneous Precipitation Reaction Rate Constant

Higher current density was observed when cadmium nitrate was used instead of potassium nitrate as the electrolyte in the electrochemical cell. The hydroxy ion produced by the reduction of nitrate ion coprecipitated with the cadmium ion in the solution. This increased the reduction reaction rate and led to higher current. This homogeneous reaction was assumed to be linearly dependent on the degree of supersaturation of cadmium hydroxide (see Equation (14)). Since the hete-

rogeneous reaction rate constants  $K_1$  and  $K_2$  were determined, the homogeneous rate constant k could be evaluated by fitting the second set of experimental data with the theoretical model to determine the value of k.

Figure 16 shows the current-density-vs.-time curves with various k values while the other parameters were held at a constant value. The current-density-vs.-time data obtained in a 0.0025M cadmium nitrate solution at the applied overpotential of -0.40V is also plotted in Figure 16. The reaction rate constant, k, was then evaluated approximately from Figure 16. The most probable homogeneous reaction rate constant was determined to be  $50~{\rm sec}^{-1}$ .

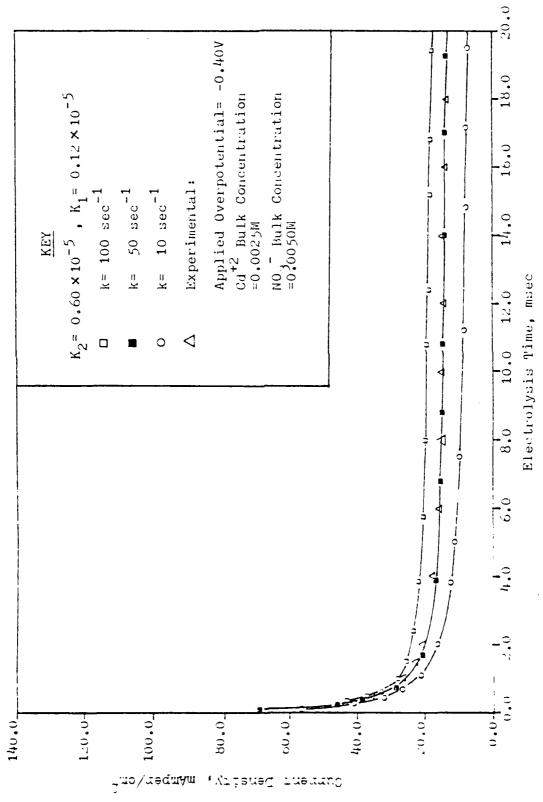

Figure 16: Computer Timulated Current-Density-vs.-Time Curves with Fixed  $K_1$  and  $K_2$  and Various Homogeneous Reaction Rate Constants.

#### CHAPTER 7

#### DISCUSSIONS AND CONCLUSIONS

## 7.1 <u>Surface Concentrations of Various Ions as Functions</u> of Time

The knowledge of the surface ion concentrations can provide information concerning the electrochemical deposition process. Although the surface ion concentrations were not available from the experiment, that information could be generated by computer simulations.

Figure 17 shows the surface concentrations of NO<sub>3</sub> and OH ions as functions of time in the absence of cadmium ion in the solution at two potentials, -0.40V and -0.60V from equilibrium potential and at a NO<sub>3</sub> bulk concentration of 0.005M. In general, the surface concentration of NO<sub>3</sub> ions decreases as time increases, while the surface concentration of OH ions increases as time increases. This is due to the electrochemical reaction (23), in which one nitrate ion reacts with two electrons and which produces three hydroxy ions.

For the case of -0.467 overpotential, the CHT concentration increases sharply from the bulk value of nearly zero

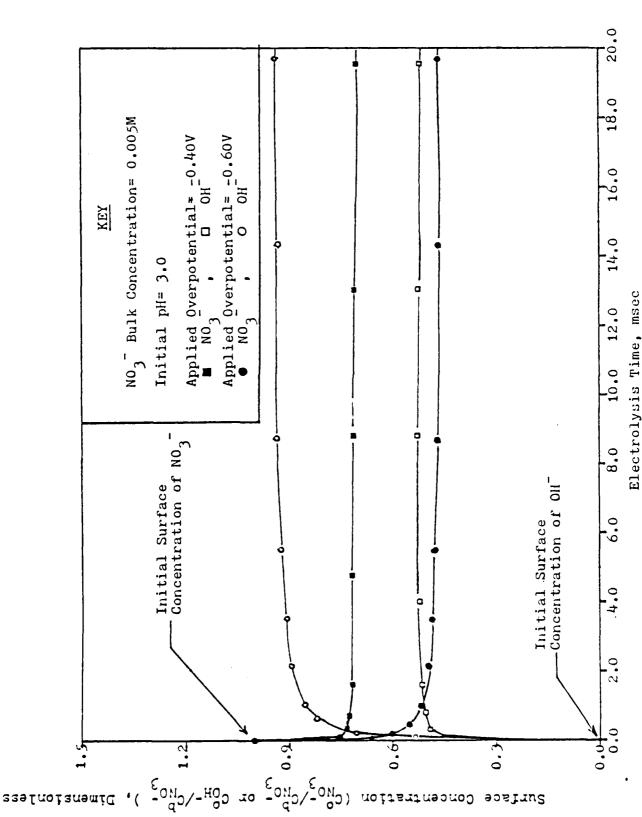

Figure 17: Surface Concentrations of NO and ON Ions as Functions of Time in the Absence of Cadmidm Ions in the Solution.

to about 0.5 dimensionless concentration units in less than 1 msec before the hydroxy ions generated are removed effectively by diffusion. Thereafter, the OHT concentration increases at a slower rate. For  $NO_3^-$  ions, the surface concentration drops to about 0.72 dimensionless concentration units from the bulk value of 1.0 in less than 1 msec and then decreases at a slower rate when the diffusion can effectively supply the reactant for the electrode reaction. The sharp changes of the surface concentrations of  $NO_3^-$  and OHT ions cause the sharp decrease of the current density in a short time period in the beginning of the electrolysis.

At a more negative overpotential of -0.60V, the increase in surface CH concentration and the decrease of NO<sub>3</sub> concentration are even more significant and last over a longer time period. The surface concentration of NO<sub>3</sub> drops to about 0.5 dimensionless concentration units and CH concentration increases to about 0.67 dimensionless concentration units in 2.0 msecs. The behavior is the consequence of the higher overall reaction rate at -0.60V. The nitrate ions were consumed at a higher rate which produced more hydroxy ions. Longer induction time is needed for diffusion to effectively supply the reactant from the bulk solution and remove the product from the electrode surface.

Similar profiles of  $NO_3^-$  and  $OH^-$  surface concentrations

at lower bulk  $NO_3^-$  concentrations were also obtained. These are shown in Figures 18 and 19.

When the electrolyte contains cadmium ions, the homogeneous precipitation reaction of cadmium ions and hydroxy ions near the electrode surface promotes the electrochemical reaction on the electrode surface in the cathodic direction. This causes the nitrate ions to be consumed at a higher rate than the case when no cadmium is present. This is shown in Figure 20 where the homogeneous reaction rate constant is 50 sec-1. It is interesting to note that the cadmium ion surface concentration increases initially and then starts to decrease. This phenomenon is explained as follows. Immediately after the electrolysis began, NO3 ions were consumed by the electrochemical reaction which produced an  $NO_3^-$  concentration gradient made the  $\mathrm{NO}_3^{-1}$  ions in the bulk solution diffused toward the electrode surface. The  $Cd^{+2}$  ions, on the other hand, moved with the  $NO_3^-$  ions in the same direction in order to maintain the elecroneutrality condition. In the meantime, the OH concentration was, however, not so high as to consume all the  $Cd^{+2}$  ions brought in by the transport process. The cadmium ions was thus accumulated and resulted in a higher value than its bulk condition. As soon as the surface concentration of CH ion raised to some value, the surface concentration of the Cd<sup>+2</sup> ions starts to decrease because of the abundant supply of OH ions consuming the cadmium ions at

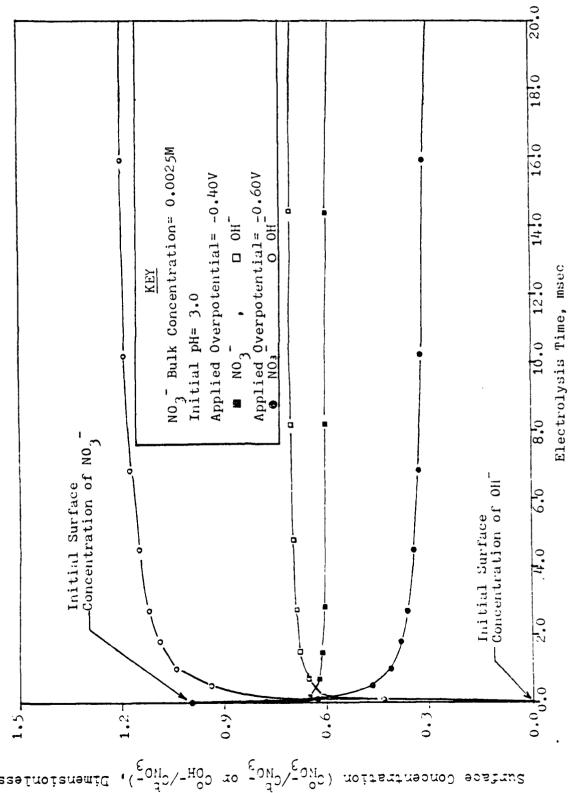

Figure 18: Surface Concentration of  ${
m NO_3^-}$  and  ${
m OH}^-$  lons as Functions of Time in the Absence of Cadmiun lons in the Solution.

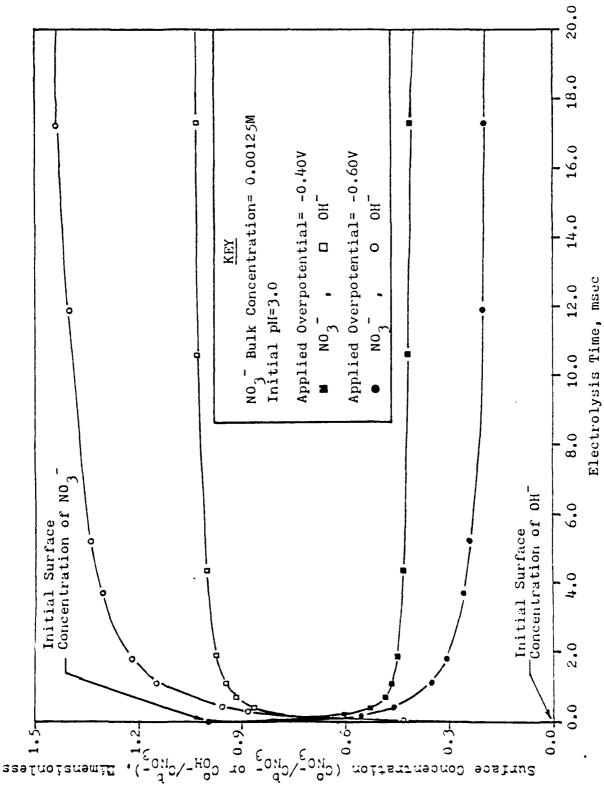

Figure 19: Surface Concentrations of  ${
m NO_3^-}$  and  ${
m OH}^-$  Ions as Functions of Time in the Absence of Cadmium Ions in the Solution.

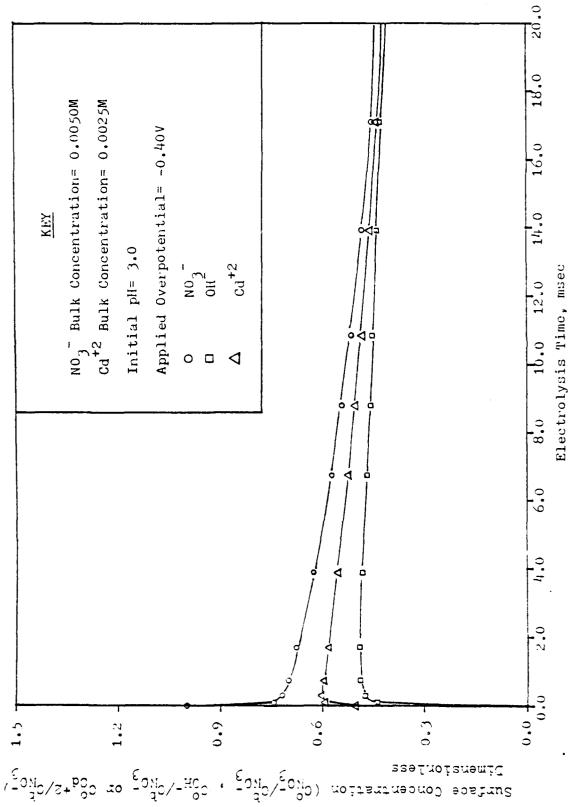

Figure 20: Surface Concentrations of  ${
m NO_3^-}$  , CH and Cd lons as Functions of Time in the Presence of Cadmium Ions in the Solution. this time.

For the nitrate ions, the surface concentration also decreases as time increases at a rate somewhat larger than that for the case of solution containing no cadmium ion. This is shown in Figure 21. Figure 21 also shows the difference in the surface concentration of the hydroxy ion between those two cases, i.e., in the presence and in the absence of cadmium ions. The initial behaviors of two cases are very similar. After this induction period, the ion concentration for the case of a solution which contains cadmium ions decreases at a more gradual rate as a result of the homogeneous precipitation reaction between cadmium and hydroxy ions.

### 7.2 Concentration Profiles of Various Ions at Various Time

For the case of solution containing no cadmium ion, the nitrate ions were consumed and the hydroxy ions were produced on the electrode, the concentration gradients were established which made the nitrate ions diffused from the bulk solution toward the electrode surface and the hydroxy ions diffused away from the electrode surface toward the bulk solution.

Figures 22 through 27 show the concentration profiles of NO<sub>3</sub> and OH ions with different applied overpotentials at some selected times. From these figures, one can see that the diffusion thickness, §, increases with time. The diffusion

thicknesses at various time are listed in Tables 2 and 3,

The concentration profiles of  $NO_3^-$ ,  $OH^-$  and  $Cd^{+2}$  ions at various time for the case of solution containing cadmium ions are shown in Figures 28 and 29. The shape of  $NO_3^-$  concentration profiles is the same as that for the case of containing no cadmium ion but the  $NO_3^-$  concentration on the surface is somewhat lower than that for the case of containing no cadmium ion. The diffusion thickness increases as time increases.

In the previous discussion of the surface concentration, the surface concentration of OH ions increases in the beginning. During that time, OH ions diffuse from the electrode surface to the bulk solution. Figure 28 shows that the surface concentration increases and the diffusion layer thickness also increases as time increases. Then the surface concentration starts to drop and the diffusion layer thickness stays at about the same value. This is shown in Figure 30. Table 4 shows the diffusion layer thickness for the diffusion of OH ions as a function of time. In Table 4, one can see that the diffusion layer thickness stops increasing as a result of the decreasing surface concentration of OH ion.

The  ${\rm Cd}^{+2}$  concentration profiles are shown in Figure 29. As the profiles indicate, for each specific time, when the

concentration near the electrode is greater than the bulk concentration of Cd<sup>+2</sup>, its value versus distance from the electrode decreases slowly in the beginning, then faster, and more slowly again before finally reaching its bulk value. At the time when the concentration values near the electrode surface are still larger than the bulk concentration, the concentration decreases to some minimum value at some distance from the electrode surface and then increases until it reaches the bulk value. The location of the minimum concentration point moves toward the electrode surface as time increases. At sufficiently long time, the minimum point finally reaches the electrode surface.

#### 7.3 Conclusions

The transport model for the electrode kinetics and the homogeneous reaction presented previously has already explained very successfully the characterestics of the current density as a function of time for both the case of solution containing cadmium ion and that without cadmium ion. This model was then used to simulate the concentration profiles for various ions involved in the reactions. The behavior of the various ions on the electrode surface and in the solution was obtained. The diffusion processes were also known after examining these concentration profiles carefully. These can be summarized as follows:

- 1. The current density decays with time after a double-layer charging. The time for this charging is so short that we can not observe it by the experiment. The decay for the current density is a result of the depletion of the nitrate ions on the electrode surface.
- 2. The current density for the case of a solution containing cadmium ions is greater than that for the case of solution containing no cadmium ion. This is because the precipitation of Cd(CH)<sub>2</sub> promotes the electrochemical reaction on the elect rode surface by consuming OH generated in this reaction.
- 3. The current density depends on the bulk concentration of nitrate ions and the applied overpotential. Increasing the NO<sub>3</sub> bulk concentration or the applied overpotential will increase the current density.
- 4. The applied overpotential is one of the factors which changes the reaction rate of the electrochemical reaction on the electrode surface. Increasing the applied overpotential will increase the overall reaction rate.
- 5. For the case of solution containing no cadmium ion, the surface concentration of NO<sub>3</sub> decreases as time increases while the surface concentration of OH increases as time increases. This is because NO<sub>3</sub> ions are consumed to produce the OH ions during the electrochemical reaction on the electrode surface.
- 6. For the case of solution containing cadmium ion, the surface concentration of NO<sub>3</sub> ion also decreases. The decreasing rate is, however, faster than that for the case

of solution containing no dadmium ion. The surface concentration of OH ion increases in the beginning and reaches a maximum. When the production rate of OH due to the electrochemical reaction is less than the consumption rate of OH due to the precipitation reaction, the surface concentration of CH starts to decrease. To maintain electroneutrality, the surface concentration of Cd ions will exceed its bulk value and then decrease to the value lower than its bulk value.

- 7. The diffusion processes for the case of solution containing no cadmium ion is that the nitrate ions diffuse from the bulk solution toward the electrode surface while the hydroxy ions diffuse in the opposite direction.
- 8. For the case of solution containing cadmium ions, the diffusion directions for both the nitrate ions and hydroxy ions are the same as that for the case of solution containing no cadmium ion. However, the cadmium ions diffuse toward the bulk solution in the beginning and then finally change direction toward the electrode surface,

## 7.4 Recommendation for Future Works

Although the model has successfully explained the cases of -0.40V and -0.60V, it is not likely valid for the case of -0.60V due to the unexpected characterestics of the current-density-vs.-time curves and the comparison of the current

density with the limiting case. When the applied overpotential is as high as -0.80V, the reaction mechanisms and electrode behavior should be identified by doing some further experiments. Furthermore, the current-density-vs.-time data at -0.60V applies overpotential for the case of solution containing cadmium ions is not available yet. It can be obtained by repeating the experimental work we decribed before. Once the data is obtained, the model can be used for comparison with the experimental data.

Finally, the configuration of the electrode in the impregnation process is not as simple as we have used in deriving the model. It is, in fact, a porous electrode in the real case. If a micro-porous electrode is possible to obtain, the experiment can be repeated to obtain the current-density-vs.-time data. Once the data are available, the transport processes can be examined for the condition of porous electrode.

## APPENDIX C

A BRIEF REVIEW OF ORTHOGONAL COLLOCATION METHOD

method of weighted residuals, MWR, is a general method for obtaining solutions to equations of change, in our case, Fick's second law. In the MWR, one assumes a trial function, usually a set of weighted polynomials, substitutes this trial function into the differential equation and then selects the coefficients of the polynomial terms by specifying that the residual be zero, on the average, at certain points. If one evaluates the differential equation at the zeros of an orthogonal polynomial, the residual will of necessity be exactly zero at these collocation points. By increasing the number of collocation points, the trial function would satisfy the differential equation at more and more points<sup>(1)</sup>.

The polynomials selected for this work are "shifted" Jacobi polynomials defined by

$$\int_0^1 x^{\beta} (1-x)^{\alpha} P_n^{(\alpha,\beta)}(x) P_m^{(\alpha,\beta)}(x) dx = 0$$
 (1)

A general diffusion problem can be formulated as

$$\frac{\partial y}{\partial t} = D \frac{\partial^2 y}{\partial x^2} + f(y), \quad 0 \le x \le 1, \quad 0 < t$$
 (2)

<sup>(1) 3.</sup>A. Finlayson & Richard Bellman (Ed.), 'Mathematics in Science and Engineering', Vol. 87, Academic Press, New York, 1972, pp 9.

with the boundary conditions of the form

$$y(0,t)=g(t) \tag{3}$$

$$y(1,t)=h(t) \tag{4}$$

and initial condition such as

$$y(x,0)=p(x)$$
 (5)

For a mass transfer problem D would be a dimension-less diffusion coefficient and f(y) would be homogeneous reaction term. Geometric considerations indicate that  $\alpha = \beta = 0$  and mathematical considerations indicate that a suitable but not unique trial function is (2)

$$y(x,t)=(1-x)y(0,t)+xy(1,t)+x(1-x)\sum_{j=1}^{N}a_{j}(t)P_{j-1}(x)$$
 (6)

The  $P_{j-1}$  of equation (6) refers to one member of a complete set of polynomials. Table 0.1 lists some Legendre polynomials, the special case of equation (1) where  $\alpha=\beta=0$ , and their roots. Note that a Legendre polynomial of legree N has N real, distinct roots on the interval 0 < x < 1,

<sup>(2)</sup> E.A. Finlayson a Richard Bellman (Ed.,, 'Mathematics in Science and Engineering', Vol. 37, Alidemic Press, New York, 1972, pp 105.

<sup>(3)</sup> John Villadsen, 'Selected Approximation Method for Chemical Engineering Problems', Reproset, Copenhagen, Denmark, 1970, pp A3 and A4.

It is evident that regardless of the value of N chosen one can always rewrite eqn.(6) in the general form

$$y(x,t) = \sum_{j=1}^{N+2} x^{j-1} b_j(t)$$
 (7)

One could at this point, as is normally the case in using MWR, obtain the coefficients  $b_j(t)$  by substitution of eqn.(7) in the differential equation whose solution is desired. However, the computer programming is greatly simplified when they are written in terms of the solution of the differential equation at the collocation points,  $y(x_i,t)$  where i=1,2,3...N+2, and each  $x_i$  is one of the N roots of the polynomial or one of the two boundary values. So in terms of the N+2 collocation points we may write:

$$y(x_{i},t) = \sum_{j=1}^{N+2} x_{i}^{j-1} b_{j}(t)$$
 (8)

We now have an approximating polynomial function which we will force to fit our partial differential eqn.(2) at the N+2 collocation points (i.e. choose the  $b_j(t)$  so that our partial differential equation is satisfied). In order to do this we will need both the first and second derivatives with respect to x. These derivatives can be calculated explicitly in terms of x since we have already defined the dependence of y upon the spatial coordinate, eqn.(c) and (8).

It is easily seen that if one considers all the co-

llocation points,  $x_i$ , equation (3) represents one member of a set of equations:

$$y(x_1, t) = \sum_{j=1}^{N+2} x_1^{j-1} b_j(t)$$
 (9)

$$y(x_2,t) = \sum_{j=1}^{N+2} x_2^{j-1} b_j(t)$$
 (10)

$$y(x_{N+2}, t) = \sum_{j=1}^{N+2} x_{N+2}^{j-1} b_{j}(t)$$
 (11)

One can see that the left-hand side is a vector of the trial solution evaluated at the collocation points. Since the term involving  $x_1^{j-1}$  depends on both i and j, a matrix will represent this term. The  $b_j(t)$  will naturally be a vector. If we let a single bar represent a vector and a bouble bar a matrix, then the set of eqns.(9) through(11) can be written as one equation in this simplified notation:

$$\overline{y(t)} = \overline{Q} \cdot \overline{b(t)} \tag{12}$$

where 
$$Q_{i,j} = x_i^{j-1}$$

The first and second derivatives with respect to x may then be obtained from equation (12):

$$\frac{\overline{dy(t)}}{dx} = \overline{C} \cdot \overline{b(t)}$$
(13)

$$\frac{d^2y(t)}{dx^2} = \overline{D} \cdot \overline{b(t)}$$
 (14)

where 
$$C_{i,j} = \frac{dx^{j-1}}{dx} \Big|_{x_i}$$
 and  $D_{i,j} = \frac{d^2x^{j-1}}{dx^2} \Big|_{x_i}$ 

It is now simple to solve for  $\overline{b(t)}$  the vector of  $b_j(t)$  coefficients, since simple rules of matrix algebra apply in this notation. Equation (12) yields

$$\overline{b(t)} = \overline{\overline{Q}}^{-1} \overline{y(t)}$$

Substituting this into eqns.(13) and(14) gives

$$\frac{\overline{dy(t)}}{dx} = \overline{C} \ \overline{Q}^{-1} \ \overline{y(t)} = \overline{A} \ \overline{y(t)}$$
 (15)

where  $\overline{A}=$   $\overline{C}$   $\overline{Q}^{-1}$  and  $\overline{B}=$   $\overline{D}$   $\overline{Q}^{-1}$  or in terms of the i-th collocation point, after some simple matrix multiplication,

$$\frac{dy(x,t)}{dx} = \sum_{i=1}^{N+2} A_{i,j} y(x_{j},t)$$
 (17)

$$\frac{d^{2}y(x,t)|}{dx^{2}} = \sum_{i=1}^{N+2} B_{i,j} y(x_{j},t)$$
 (18)

One can therefore express the spatial derivatives in terms of the trial function at the N+2 collocation points.

Equation (16) can be directly applied to some diffusion process such as that described by eqns.(2) through (5). Equation (2) becomes

$$\frac{\overline{dy(t)}}{dt} = k\overline{\overline{y}(t)} + \overline{f(y(t))}$$
(19)

where the vector  $\overline{\mathrm{dy}(\mathtt{t})}/\mathrm{dt}$  represents the set of time derivatives at the N+2 collocation points. We note that there is no explicit spatial (x) dependence in eqn.(19). By assuming an explicit polynomial in x, eqn.(6), and evaluating it at specific values, the collocation points, the problem is reduced from a partial differential equation with two independent variables to a set of ordinary differential equations.

One can expand eqn.(19) into its separate members to solve the problem. For the i-th collocation point we can write, according to eqn.(19),

$$\frac{dy(\mathbf{x},t)}{dt} = \mathbf{x} \left( \sum_{j=1}^{N-2} \mathbf{B}_{\underline{i},j} \ y(\mathbf{x}_{\underline{i}},t) \right) + f(y(\mathbf{x}_{\underline{i}},t)), \quad (20)$$

for i = 1, 2, 3, ... i + 2.

One now considers the conditions at the boundaries  $x_1=0$  and  $x_{N+2}=1$ . Since these values are known from the original problem i.e. eqns.(3) and (4) one can subtitute the boundary conditions in eqn.(20) to obtain

$$\frac{dy(x,t)}{dt} = k \left[ B_{i,1} \cdot g(t) + B_{i,N+2} \cdot h(t) + \sum_{j=1}^{N+1} B_{i,j} y(x_j,t) \right] + f(y(x_i,t))$$

for i = 2,3,4...N+1.

One should note that g(t) and h(t) are included so that the boundary conditions may be time dependent in which case g(t) and h(t) would be known or easily obtained. The diffusion problem has been transformed into a set of N simultaneous first order ordinary differential equations in N unknowns with initial conditions and can be solved numerically by a number of standard methods on a computer.

Evaluation of the current at an electrode,  $i= nFAD\frac{\partial c}{\partial x}\Big|_{ix=0}$ , can be obtained directly from eqn.(17) once the concentration profile is obtained.

## APPENDIX D

COMPUTER PROGRAMS USING ORTHOGONAL COLLOCATION METHOD

```
THIS PROGRAM SOLVES EQUATIONS (50) THROUGH (55) WITH TWO
    INITIAL CONDITIONS USING SPLINE COLLOCATION METHOD FOR THE
    CASE OF THE ELECTROLYTE CONTAINING HO CADMIUM ION.
    EQUATIONS (50) AND (51) ARE DISCRETIZED FIRST-ORDER
    ORDINARY DIFFERENTIAL EQUATIONS WHICH ARE SOLVED BY AN
    SEMI-IMPLICIT INTEGRATION SUBROUTINE CALLED DIFSUB USING
    GEAR'S ROUTINEL EQUATIONS (52) THROUGH (53) ARE SOLVED STRUCTURED BY A SUBROUTINE CALLED ASYSTM WHICH COMES
    FROM INSU SUBBOUTINE PACKAGE TO OBTAIN THE SUBPACE
    CONCENTRATIONS OF MITRATE AND HYDROAY IONS. EQUATIONS (54)
    AND (55) ARE THEIR BULK VALUES. THE CONCENTRATION PROFILES
    THUS OBTAINED ARE THEN USED TO CALCULATE THE CURRENT
    DENSITY BY EQUATION (56). THE CURRENT DENSITY DATA ARE
    THEN USED TO FIT WITH THE EXPERIMENTAL DATA TO IDENTIFY
    THE CATHODIC AND ANODIC REACTION RATE CONSTANTS OF THE
    SUBPACE REACTION.

SUBROUTINE INTEGRATES A SET OF A ORDINARY DIFFERENTIAL FIRST
ORDER EQUATIONS AS DESCRIBED IN EQUATIONS (50) AND (51) OVER
ONE STEP OF LENGTH H AT EACH CALL. H MAY BE INCREASED OF
DECREASED WITHIN THE RANGE HAIN TO HEAK IN ORDER TO ACHIEVE
AS LARGE A STEP AS POSSIBLE WHILE NOT COMMITTING A SINGLE
STEP ERBOR WHICH IS LARGER THAN 823 IN THE L-2 NORM, WHIRE
EACH COMPONENT OF THE ERROR IS DIVIDED BY THE COMPONENTS OF
ZKKY.
THE PROGRAM SALLS FOUR SUBROUTINES NAMED
     OIFFUN (T,Y,DY)
     (L, m, E, k S) VELTAE
     SOLVE (NH, PUL, B, K)
     PEDERV(T,Y,PN,M)
THE FIRST, DIFFUN, EVALUATES THE DESIVATIVES OF THE DEPENDANT
VARIABLES STORED IN Y(1,1) FOR I=1 TO N, AND STORES THE
DERIVATIVES IN THE ARRAY DY. THE SECOND IS CALLED ONLY IF
MF IS SET TO 1 OR 2 FOR STIFF METHODS. IT PERFORMS A FLAST
STAGE OF GAUSSIAN ELIMINATION BOUTINE OF THE N BY N MATRIX
STORED IN THE ARREA WIND, MY WARRA BHT HI CEROTE
SUBSTITUATION PROCESS OF THE GAUSSIAN ELIMINATION ADJITUAL.
PEDERV IS USED ONLY IF MF IS 1, AND STURES THE PARTIAL
DEBIVATIVES OF THE DIFFERENTIAL EQUATIONS PROVIDED BY DIFFUN-
--- PARAMETERS ---
N=THE NUABER OF FIRST ORDER DIFFERENTIAL EQUATIONS.
T= IHE INDEPENDENT VARIABLE.
Y=AN B BY N ABBAY CONTAINING THE DEPENDENT VARIABLES AND
  THEIR SCALED DERIVATIVES. THE DEPENDENT VARIABLES ARE
  STURED IN Y (1,I), I=1 TO N.
SAVE=A BLOCK OF AT LEAST 12*N PLOATING POINT LOCATIONS USES
     BY THE SUBROUTINE.
H=THE STEP SILL TO BE ATTEMPTED ON THE NEXT STEP.
HMIN=THE MINIMUM STEP SIZE THAT WILL BE USED FOR THE
     INTEGRATION.
MMAA=THE MAXIMUM SIZE TO WHICH THE STEP WILL BE INCREASED.
EPS=THE ERROR TEST CONSTANT.
MF=THE METHOD INDICATOR.
            AN ADAMS PREDICTOR CORRECTOR IS USED.
            A MULTI-STEP METHOD SUITABLE FOR STIFF SYSTEMS
     1
            IS USED.
            THE SAME AS CASE 1, EXCEPT THAT THIS SUBBOUTING
            COMPUTES THE PARTIAL DERIVATIVES BY WIMERICAL
            DIFFERENCING OF THE DESIVATIVES.
TRABE TO THE SHIFT OF HEAD CHOITAGE WELL IN TO THE SHEEF
     EACH Y SEEN SO FAR.
LATERITES LET ENTATION HOTHER STREETS R SO YANGA RAFRORES
      UNE SIEF ERBOR IN EACH COMPONENT.
KFLAG=A COMPLETION CODE. I HEARS THE STEP AND SUCCESSFUL.
```

0

JSTART=AU IMPUT INDICATOR.

MAKDER = THE MAKIKIM DEPIVATIVE THAT SHOULD BL MEED. PW = A BLOCK OF AT LEAST N \* \* 2 FLOATING POINT LOGATIONS.

THIS PROGRAM SOLVES EQUATIONS (48), (49), AND (52) THROUGH
    (55) WITH TWO INITIAL CONDITIONS USING SPLINE COLLOCATION
                                                                     C
    METHOD FOR THE CASE OF THE BLECTROLYTE CONTAINING CADMIUM
    IONS. IN THIS CASE, THE TWO SUBROUTINES, DIFFUN AND PEDERV,
    CALLED BY THE INTEGRATION SUBROUTINE, DIFSUB, HAVE TO BE
    CHANGED. MEANAHILE, THE MAIN PROGRAM AS WELL AS THE OTHER SUBBOUTINES STAY THE SAME. THE CONCENTRATION PROFILE OF
    THE CADMIUM ION MAY BE OBTAINED BY THE ELECTRONEUTRALITY
    CONDITION. THE CUBRENT DENSITY DATA ARE CALCULATED IN THE
C
    SAME WAY BY EQUATION (56). THE HETEROGENEOUS REACTION RATE
C
    CONSTANTS OBTAINED BY LAST PROGRAM ARE USED TO IDENTIFY
C
    THE HOADGENEOUS REACTION RATE CONSTAIN BY FITTING THE
    CALCULATED CUBRENT DENSITY DATA WITH THE EXPERIMENTAL
C
                                                                     C
    DATA.
